1.0 INTRODUCTION

1.1 Overview

This baseline human health risk assessment (risk assessment) was conducted to evaluate potential adverse risks to human populations resulting from exposures to hazardous substances at the Himco Dump site in Elkhart, Indiana. By definition, a baseline risk assessment is limited to conditions under the no-action alternative, that is, in absence of any remedial actions to control or mitigate releases, including institutional controls.

The methods and procedures used in this risk assessment are consistent with U.S. Environmental Protection Agency (USEPA) guidance, including the Risk Assessment Guidance for Superfund, Volume I - Human Health Evaluation Manual (RAGS) (USEPA 1989a), the Exposure Factors Handbook (USEPA 1989b), the Superfund Exposure Assessment Manual (USEPA 1988a) and Standard Default Exposure Factors in OSWER Directive 9285.6-03 (USEPA 1991c). Additional USEPA guidance and other technical information have also been used and are referenced where appropriate.

1.2 Site Background

The Himco Dump site (site) is a closed landfill located at County Road 10 and Nappanee Street Extension in the city of Elkhart, Indiana. The site is approximately 50 acres and is bordered by roads and residences on the south and east sides and tree lines and surface water bodies on the north and west sides. Figure 1-1 illustrates the location and boundaries of the site. Figure 1-2 indicates the major features of the site as it currently exists.

The Himco Dump site was privately operated by Himco Waste Away Services, Inc. and used as a landfill. The landfill had no liner, leachate or gas recovery system. Wastes were placed directly onto the ground surface or into five trenches each 10 to 15 feet deep. The trenches were also used for burning of paper wastes. Wastes were covered daily with sandy soil from the quarry pit, from on-site excavated ponds or from the periphery of the site. Wastes consisted primarily of calcium sulfate (from a pharmaceutical source) with lesser amounts of other pharmaceutical, industrial, construction and household wastes. The landfill was operated until 1975 when it was closed and a cover of calcium sulfate and sand was placed over the landfill.

In 1974, residents near the site complained to the State Board of Health about color, taste and odor problems in their shallow drinking water wells. In response, their shallow (22 feet) wells were replaced by deeper (152 to 172 feet) wells. In 1981, the U.S. Geological Survey (USGS) in cooperation with the Indiana Department of Natural Resources and the Elkhart Water Works reported on a three-year groundwater resources study. The USGS characterized the extent of a potential leachate plume (based on concentrations of bromide) from the site.

In 1984, a USEPA field investigation team (FIT) conducted a site inspection of the dump and determined that groundwater was impacted by metals and volatile and semivolatile chemicals. At the time of the site inspections, leachate seeps were observed but not characterized.

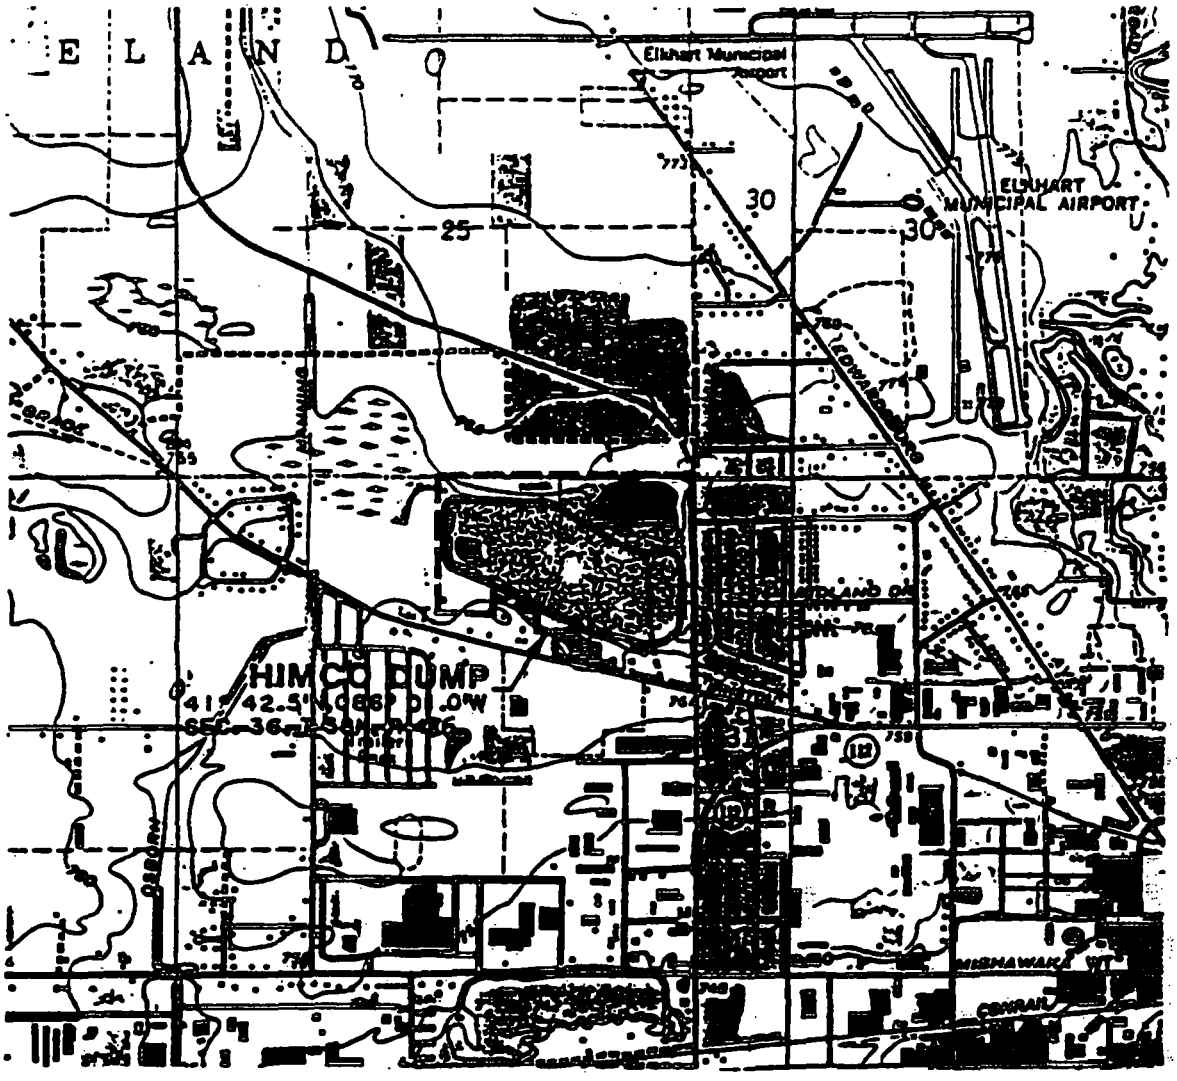

FIGURE 1-1 SITE LOCATION MAP HIMCO DUMP SITE ELKHART, INDIANA

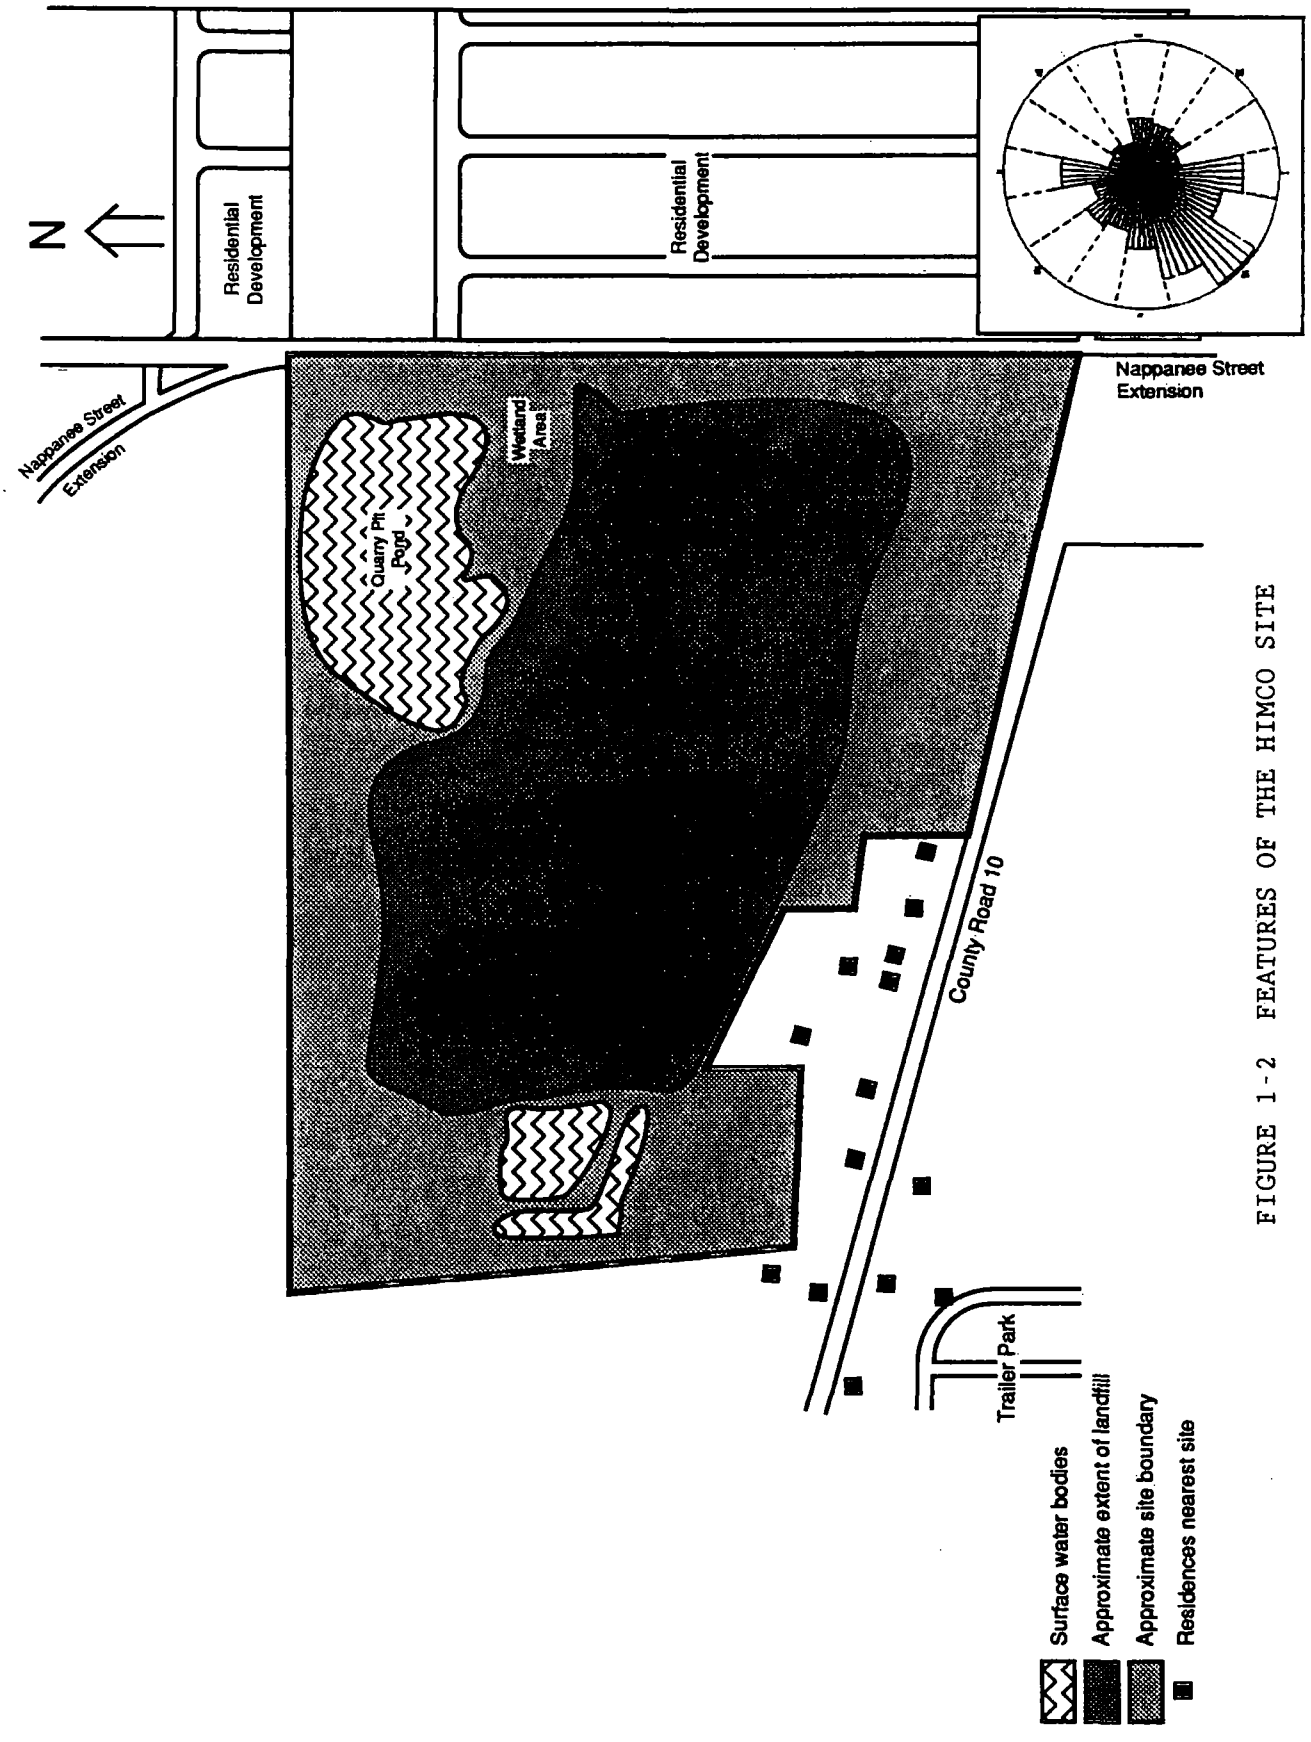

FIGURE 1-2 FEATURES OF THE HIMCO SITE

In 1988, the Himco Dump site was proposed for the National Priorities List (NPL) and in February 1990 was designated a final NPL site.

In September 1989, SEC Donohue initiated a Remedial Investigation/Feasibility Study. During the investigation two emergency response actions were undertaken. In April 1990, USEPA's Emergency and Response Branch sampled residential wells downgradient of the site and as a result those residents were provided municipal water service by November 1990. In May 1992, a site assessment focused on the south/southwest section of the landfilled area where quantities of volatile compounds were discovered in leaking drums. Seventy-one, 55-gallon drums were subsequently removed.

1.3 Scope of the Risk Assessment

The scope of this risk assessment is limited to potential risks to human populations exposed to environmental contamination at the Himco Dump site. The data utilized in this evaluation are limited to data collected during Phase I and Phase II of the Remedial Investigation (RI). This human health evaluation together with the environmental evaluation (ecological assessment) comprise the baseline risk assessment (or endangerment assessment) for the site. The environmental evaluation is documented in a separate report (Life Systems 1992).

1.4 Organization of the Risk Assessment Report

The format of this report follows USEPA's (1989a) recommended outline and is organized into eight sections, including this introductory section.

Section 2.0, Identification of Chemicals of Potential Concern, summarizes the environmental data collection and details the selection of chemicals of potential concern. Section 3.0 summarizes the exposure assessment including the identification of potentially exposed populations and evaluation of current and future exposure pathways. The exposure assessment also provides estimates of environmental concentrations of contaminants at exposure points and contaminant intakes for specific pathways. The toxicity assessment, Section 4.0, summarizes the carcinogenic and noncarcinogenic health effects related to the chemicals of potential concern. Section 5.0, Risk Characterization, combines the results of the exposure and toxicity assessments and characterizes the potential for adverse health effects. Section 6.0 is an assessment of the uncertainties related to this risk assessment. Section 7.0 is a summary of the risk assessment and Section 8.0 is the reference list.

This report also contains six appendices. Appendix 1 provides additional detail on the sampling data. Appendices 2 and 3 describe the methodology and calculations for the evaluation of the air pathway. Appendix 4 documents the calculation of exposure point concentrations. Appendix 5 contains detailed calculations of exposure and risk for the exposure scenarios quantified in this risk assessment. Appendix 6 contains expanded toxicity summaries for chemicals contributing to risk.

2.0 IDENTIFICATION OF CHEMICALS OF POTENTIAL CONCERN

Chemicals of potential concern are chemicals present at the site that could pose a risk of adverse health effects to exposed humans. The selection of these chemicals is based mainly on the results of chemical analyses of environmental media from the site. Chemicals of potential concern normally include all toxic chemicals that have been released by waste disposal at the site, but may also include naturally-occurring toxic chemicals and toxic chemicals that have reached the site by environmental transport from other sources. If the risk assessment indicates that one or more of these chemicals poses sufficient risk to be of concern, then more detailed evaluations of the relative magnitude of the risks from each source (on-site waste, naturally-occurring chemicals, chemicals transported from other sources) may be needed to provide the basis for evaluation of remedial alternatives and other risk management decisions.

2.1 Overview of Sampling

2.1.1 Historical Data

The following information, obtained from Donohue Work Plans (Donohue & Associates 1990a, 1991a), summarizes site sampling activities prior to the RI.

The Indiana State Board of Health (ISBH) analyzed residential wells immediately south of the site in 1974 in response to residents' complaints about color, taste and odor problems. The analyses indicated high levels of manganese in the shallow wells (approximately 22 feet deep), and this resulted in the drilling of deeper wells (152 to 172 feet deep).

In 1981, the USGS conducted a groundwater resources study which determined the extent of a potential leachate plume (bromide) from the site. The plume (evaluated 1979 through 1987) appeared to be extending and moving to the south-southeast toward the St. Joseph River.

In 1984, the FIT determined that groundwater downgradient of the site was impacted by metals, volatiles and semivolatiles. Detected metals included aluminum, arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, manganese, mercury, nickel, selenium and zinc. Detected volatiles and semivolatiles included acetone, benzene, phenol, freons, 4-methylphenol, trans-1,2-dichloroethane, 2-butanone, chloroethane and pyrene.

2.1.2 Remedial Investigation Data

During the RI, sampling and analysis of surface, subsurface and suspected wetland soils, groundwater, surface water and sediments were undertaken to determine the magnitude and extent of contamination and to supply data adequate for a risk assessment. The remedial investigation also included excavation of test pits, geotechnical analysis and waste mass gas sampling (landfill and residential). The monitoring associated with the Himco RI was accomplished in two phases: Phase I (October 1990 through February 1991) and Phase II (September and November 1991). Table 2-1 summarizes the number of

TABLE 2-1 SUMMARY OF RI SAMPLES - PHASE I AND II

Medium	Number of Phase I Samples	Number of Phase II Samples	Total Number of Samples
Landfill Cap/Miscellaneous Soil	12	11	23
Wetland Soil	16	3	19
Soil Sample from Soil Boring - Chemical	30	3	33
Surface Water	12	9	21
Sediment	12	9	21
Leachate	0	4	4
Monitoring Wells	36	19	55
Residential Wells	8	0	8

samples taken during each phase on a medium by medium basis. Figure 2-1 indicates site locations across the site where samples were taken. These sampling efforts are described in detail in the RI Report (SEC Donohue Inc. 1992) and are briefly summarized in the following sections.

Soil Sampling

A series of surficial soil samples (GS01...GS12) were collected in November 1990 from depths as shallow as 3 to 9 inches and as deep as 8 to 16 inches from the existing landfill cover. Depth varied dependent upon the thickness of the overlying topsoil and sand cover. This cover material was removed prior to sampling at each location. Soil was also sampled when six shallow observation wells were installed on or adjacent to the site in November 1990. Samples (GT01...GT06) were taken at two-foot intervals from the surface to a maximum depth of 16 feet and correspond to well numbers WT101 through WT106. All samples were analyzed for the inorganic analytes on the Target Analyte List (TAL) and the compounds on the Target Compound List (TCL) including volatiles and semivolatiles, polychlorinated biphenyls (PCBs) and pesticides by Contract Laboratory Program (CLP) Routine Analytical Services (RAS). Selected samples were analyzed for grain size and other geotechnical analyses.

During Phase II additional surficial soil samples (HS01...HS09) were taken along the dirt bike trail, near the L-shaped pond and in the area south of the landfill cap. Two soil samples were also taken in the area southeast of the landfill (Trench 3) and were analyzed for all TCL/TAL analytes from Trench 3 (at 2 feet and 6 feet).

Nineteen soil samples (WS01...WS19) were taken in both phases from the areas suspected (at the time of sampling) to be wetlands. Six samples were from the area surrounding the two small surface water bodies, four from the area north of County Road 10 and nine from the area adjacent to the quarry pit pond. Samples were composited typically from 0 to 18 inches at each location. Samples were analyzed by RAS for TCL and TAL chemicals.

Groundwater Sampling

A total of 34 groundwater wells were sampled during the RI. The locations of these wells are indicated on Figure 2-2. The wells sampled included 11 wells installed during the RI, 23 USGS wells installed in 1977 and 1979. During both phases wells were analyzed for the analytes on the TCL/TAL, bromide and additional water quality parameters.

Groundwater samples (RW01...RW08) were collected in October 1990 from five residential wells immediately south of the site and one residential well immediately south of County Road 10 (Figure 2-1). At the time of sampling, two of these residences still had access to older shallow wells in addition to their deep wells, and these two shallow wells were also sampled. The deep water well samples were taken at the tap at the kitchen sink, or if available,

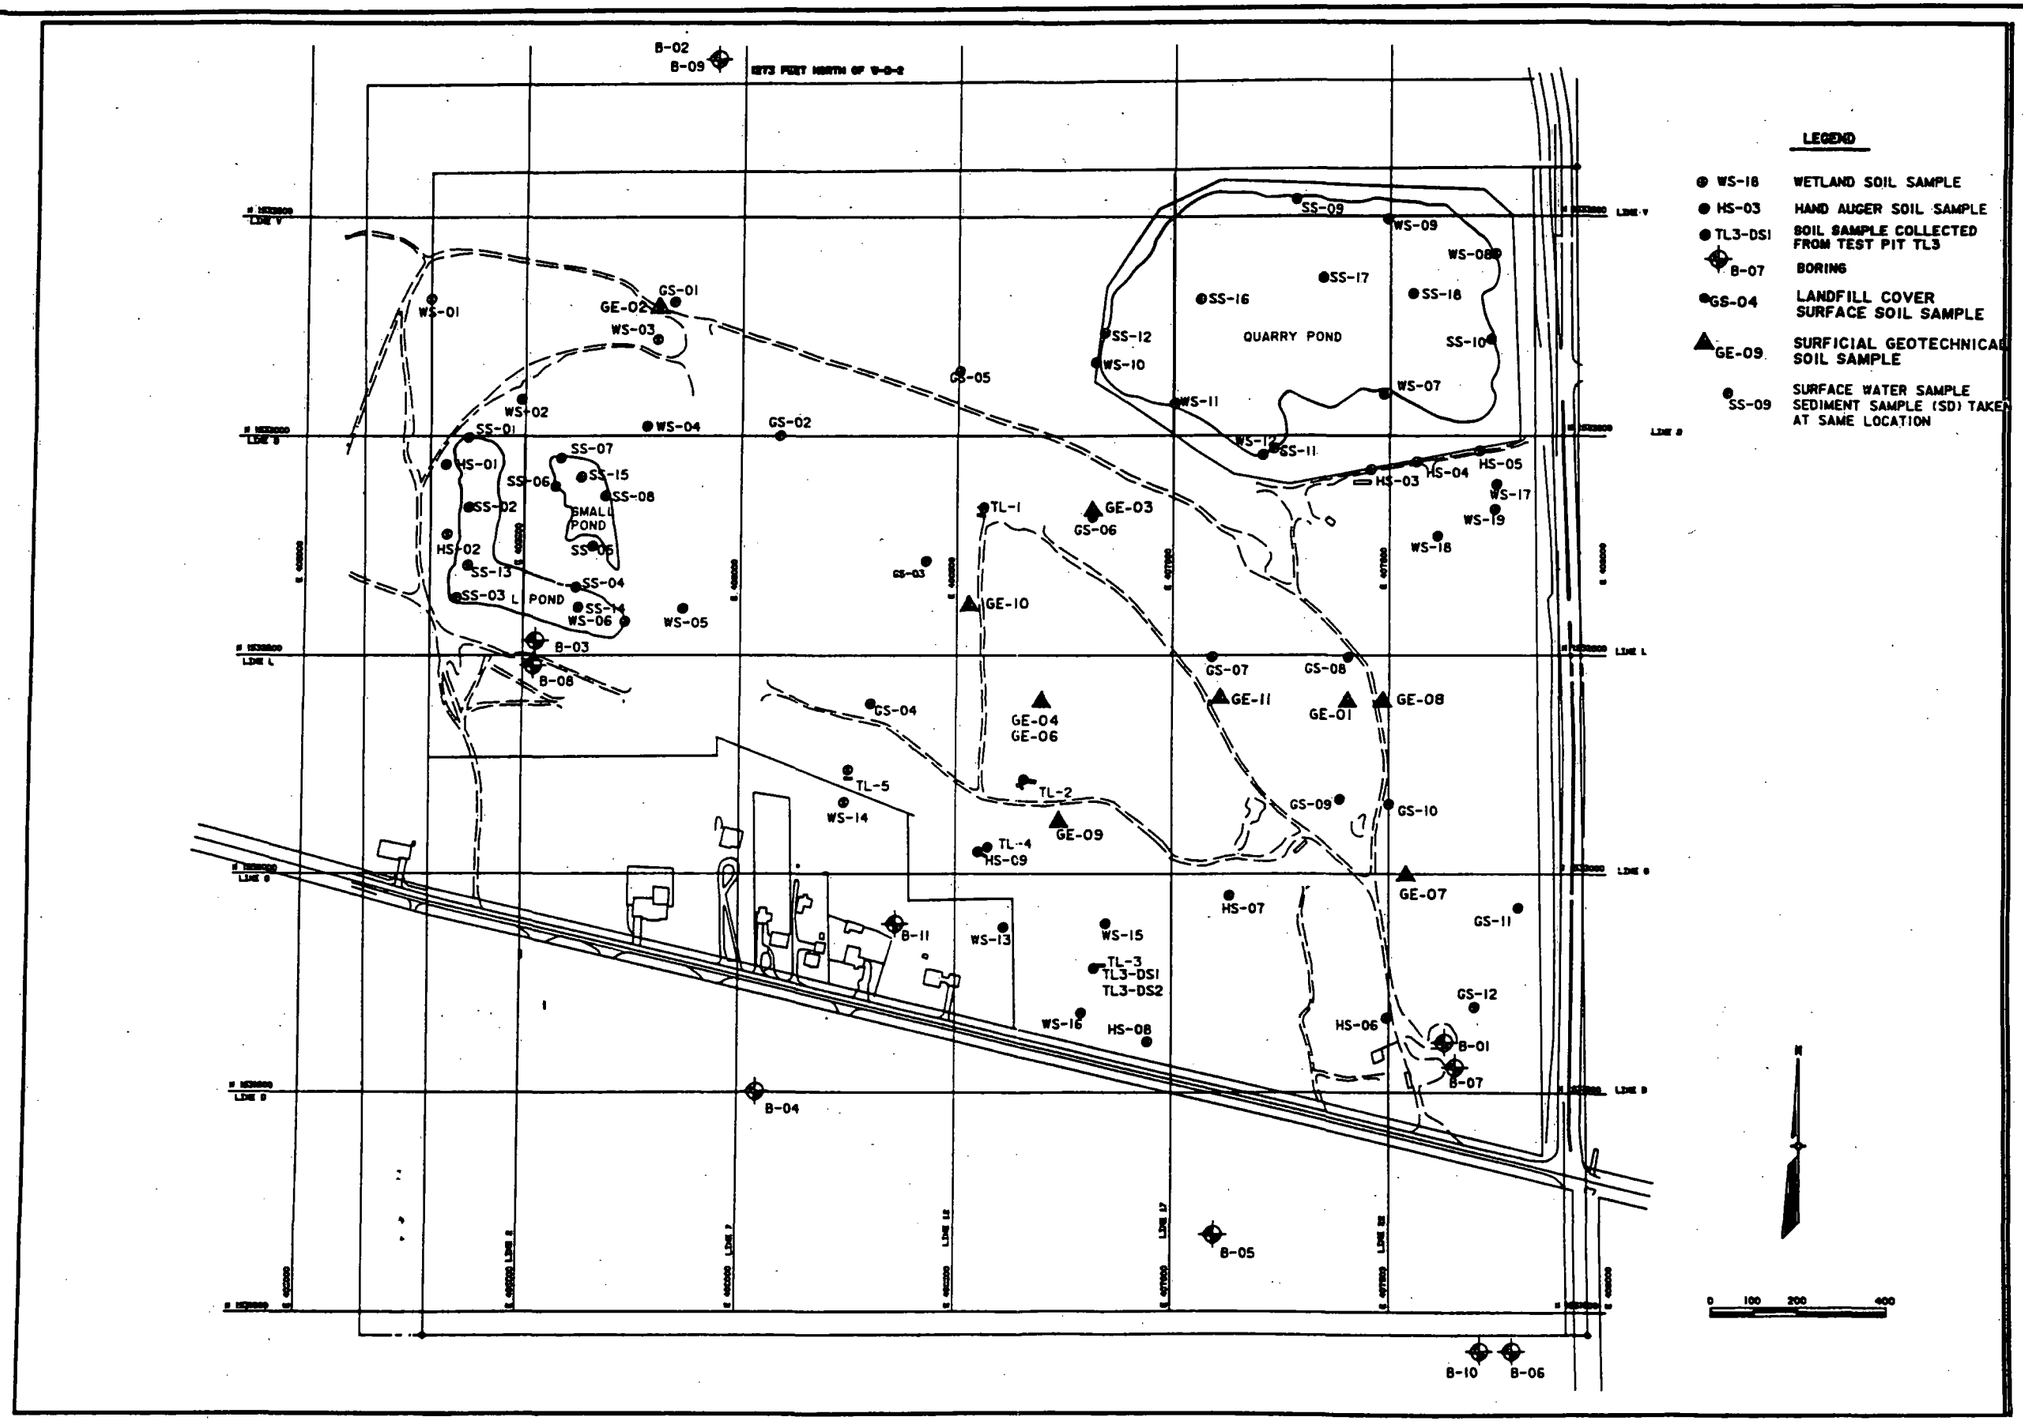

FIGURE 2-1 REMEDIAL INVESTIGATION SAMPLING LOCATIONS

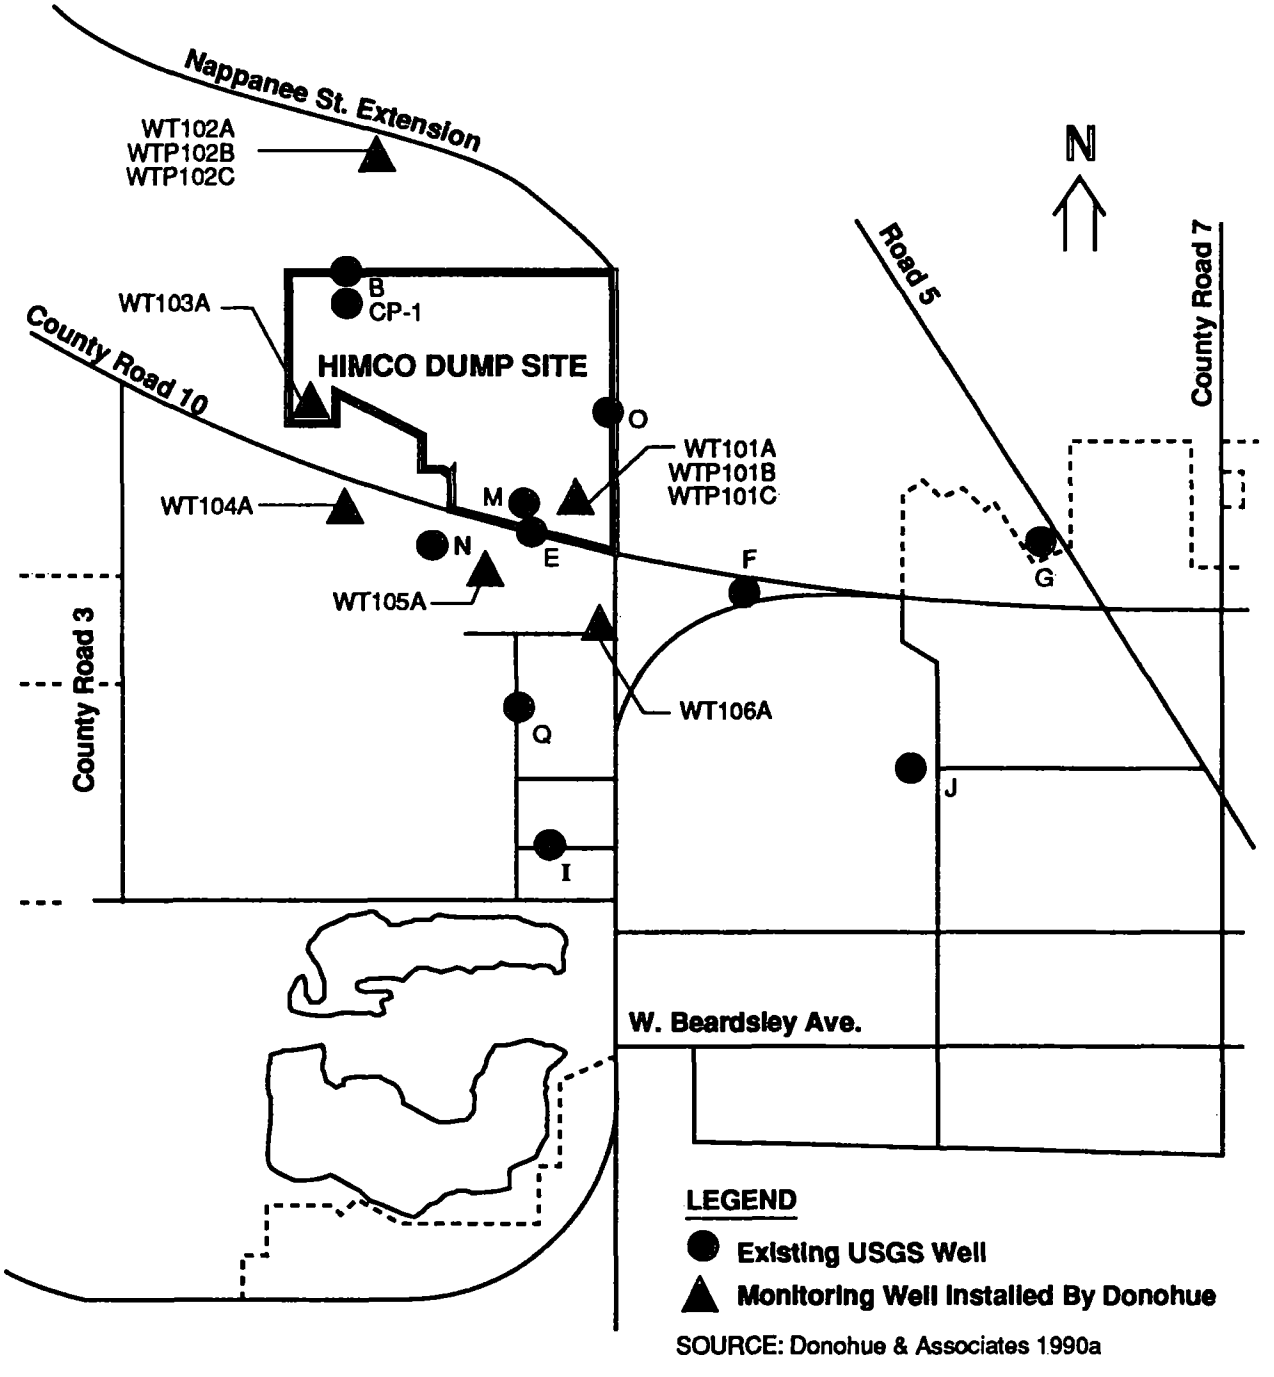

FIGURE 2-2 GROUNDWATER WELL LOCATIONS

available, at a tap in the basement ahead of the water softener. Shallow wells were sampled by bailing. These samples were analyzed by Special Analytical Services (SAS) for all TCL and TAL chemicals.

Trenching/Leachate Collection

Thirty-three test pits (approximately twenty-five feet long) were excavated to a maximum depth of approximately 15 feet (unless the water table was reached first) either on the landfill cap (Phase I) or in the south of the landfill cover (Phase II). The excavation uncovered several crushed drums and drum lids, scrap metal grips, sheet metal, refrigerator condensers and other miscellaneous metallic items. After information on the wastes observed in the pits was collected, the pits were backfilled. During Phase II leachate samples were collected from trenches 1 through 5. These samples were analyzed for TAL/TCL analytes and water quality parameters.

Surface Water and Sediment Sampling

A total of 18 surface water and sediment samples were collected from the three ponds on site. During Phase I, twelve locations were sampled. The locations were selected so that each north, south, east and west shoreline was sampled. The surface water samples were collected prior to the sediment samples and on different days. Sediment samples were collected at the same locations as the surface water samples, approximately 2 to 3 feet offshore and at water depths from 0 to 2 feet. All samples were analyzed for all TAL and TCL chemicals by RAS. Water quality parameters were also determined for all surface water samples. During Phase II, nine surface water and sediment were collected, six from the three on-site ponds and three samples from a background pond located approximately two miles northeast of the site.

Waste Mass Gas Survey

A waste mass gas survey was completed to characterize the extent and degree of contamination on site. Twelve soil cap locations on site were sampled at 2-to 3-foot depths. The survey detected compounds indicative of disposal of aerosol cans (1,1,2-trichloroethane and 1,2,2-trifluoroethane), solvents (methylene chloride, acetone, benzene, toluene and 1,1,1-trichloroethane) and landfill gas (carbon disulfide).

Residential Gas Sampling

The basements of four residences on County Road 10 were screened for the presence of landfill gases (methane and hydrogen sulfide). No landfill gases were detected.

2.2 Data Quality

All analyses of data collected during the RI sampling were reviewed and validated by USEPA, according to procedures described in USEPA (1988b,c). During this effort USEPA reviewed data qualifiers as reported by the

laboratory, reviewed quality control information and concluded whether the data were usable. As a result, the following decisions were made regarding the use of the data for risk assessment purposes:

- Chemicals which were analyzed for but were not detected were reported with a "U." These sample results, including those qualified with a "UJ," were used in the risk assessment as nondetects.

- Any concentration values for organics or inorganics deviating in minor ways from CLP requirements for holding times, analytical spikes, duplicates or other quality control parameters were considered estimated values and were reported with a "J." These values were used in the risk assessment as if they were unqualified.

- Any inorganic concentration values reported as less than the contract required detection limit (CRDL) but greater than the instrument detection limit were qualified with a "B." These values were used in the risk assessment as if they were unqualified.

- Any detected value for an organic chemical which was also detected in the associated blank was qualified with a "B." The sample value was compared to the blank value according to the procedures in USEPA (1988c).

- All values qualified with an "R," indicating the sample results were rejected by the validation personnel, were removed from the data set and were not used in this risk assessment.

2.3 Approach for Identifying Chemicals of Potential Concern

Figure 2-3 diagrams the approach used to select contaminants of potential concern at Himco. As shown, any chemical detected at least once in any on-site soil, groundwater, leachate, surface water or sediment sample was considered to be a possible chemical of concern. Samples considered to be representative of background (i.e., soil at boring locations 02, 04, 05 and 06, groundwater at upgradient wells WT102A through WT102C and WTB, sediment/surface water locations 19 through 21) were not used in the selection process. Due to the uncertainty regarding the integrity of the residential wells, those samples were also not included in the data set used for selection of chemicals of potential concern. The RI concluded that these wells were not representative of aquifer quality due to questionable development (SEC Donohue Inc. 1992).

Table 2-2 lists chemicals never detected in any sample collected during the RI. Table 2-3 summarizes all chemicals detected at least once. Some chemicals listed in Table 2-3 were subsequently excluded from quantitative evaluation for reasons discussed below.

Exclusion Based on Beneficiality

Some inorganic chemicals detected at the site occur naturally in the body (calcium, copper, iron, magnesium, manganese, potassium, selenium, sodium and zinc), and moderate intakes are considered beneficial or essential to good

health (NAS 1989). Hence, these essential nutrients detected may not be of concern to human health. The average detected concentration of these chemicals in surface soil and groundwater was used to estimate a maximum daily intake of these chemicals, based on an assumed intake of 120 mg/day of soil and 2 L/day of water. If the estimated intake of a chemical (mg/day) from both soil and water did not exceed the Recommended Dietary Allowance (RDA) for an adult (>18 years old) (NAS 1989), the chemical was eliminated as a chemical of potential concern. Calcium, copper, magnesium, manganese, potassium, selenium, sodium and zinc were thus eliminated as chemicals of potential concern (see Table 2-4). The only essential nutrient retained is iron.

Tentatively Identified Compounds

A number of tentatively identified compounds (TICs) were reported in the database (see Table A1-6). For TICs the identities of these chemicals assigned by the laboratory may be inaccurate. In addition, the concentrations reported are highly uncertain. In general, TICs are not evaluated quantitatively. Eliminating TICs from the risk evaluation is a source of some uncertainty in the risk assessment. This is discussed in Section 6.0 of this report.

2.4 Summary of Chemicals of Potential Concern

After excluding chemicals never detected, essential nutrients and TICs, the chemicals remaining are considered chemicals of potential concern for the Himco Dump site. These chemicals are listed in Table 2-5.

Appendix 1 provides the sampling results for all the chemicals at locations on site or potentially impacted by site contaminants including frequency of detection, ranges of detected concentrations and the range of detection limits. Also included are the sampling results at all background locations. Table A1-3 includes results for soil samples at all four background locations at all depths 02, 04, 05, 06).

It should be noted that exclusion of a chemical because it was never detected may introduce some uncertainty into the risk assessment. This is especially true if the detection limit was sufficiently high (i.e., insensitive) such that a health risk might occur at levels equal to or less than the detection limit. The uncertainty introduced by exclusion of never detected chemicals is discussed in Section 6.0.

Heptachlor
Polychlorinated biphenyl - Aroclor 1248

NON-CLP CHEMICALS:

Bromide, dissolved
Chloride
Nitrogen, ammonia
Nitrogen, nitrate & nitrite
Phosphorus
Sulfate

3.0 EXPOSURE ASSESSMENT

Exposure is defined as the contact between a human and a chemical in the environment. The amount of contact (the dose) depends upon the level of the chemical in the environment and the extent of contact between humans and contaminated media. The exposure assessment presented in this section describes the pathways by which humans may be exposed to chemicals of potential concern at the Himco Dump Site and provides quantitative estimates of dose for the most important of these pathways.

3.1 Characterization of the Exposure Setting

This section summarizes site information with respect to the physical characteristics and characteristics of the populations (both current and hypothetical future) on and near the site. The source of the following information includes data collected by SEC Donohue Inc. during the RI process, the Soil Conservation Service, the U.S. Geological Survey, the U.S. Census Bureau, a site visit conducted by Life Systems, Inc. personnel in October 1990 and city and county maps of the area.

3.1.1 Physical Setting

The Himco Dump site is a closed landfill located at County Road 10 and the Nappanee Street Extension in the Town of Elkhart in Elkhart County, Indiana. The site is approximately 50 acres and is bounded on the east by Nappanee Street Extension, on the south by County Road 10 and private residences, on the west by a tree line and an "L"-shaped pond and on the north by a tree line and a quarry pit pond (Figure 1-2). Approximately two-thirds of the site has been landfilled.

Climate

Elkhart County has a typical mid-continental climate with large temperature variations between summer and winter. The average monthly temperature in Elkhart County ranges from 23 F in January to 72 F in July. The temperature extremes are from 10 F to 98 F. The mean annual rainfall and snowfall are 34.5 and 36 inches, respectively. Snowfall normally occurs from November to March (SEC Donohue 1992).

Meteorology

The wind rose from the South Bend/St. Joe weather station (approximately 15 miles from Elkhart) is shown in the lower right-hand corner of Figure 1-2. This indicates the prevailing wind direction is from the southwest. The average windspeed is 5.03 mph (GSC 1989).

Geologic Setting

The site is within an area that has been glaciated four times during the Pleistocene Epoch. After each glaciation, the ice receded and melt-water streams eroded the glacial deposits. As a result, the bedrock is covered with stratified and unstratified drift.

The surficial geology is characterized by valley train outwash deposits (average thickness of 175 feet) bounded on the north and south-southeast by till plains of stratified drift and ground-moraine deposits. The till deposits in the area consist of silty sand interbedded with clay and silt layers. No indication of this silt and clay layer, however, was detected beneath the site. The bedrock geology consists of Devonian and Mississippian shales. Depth to shale ranges from 85 to 500 feet and averages 175 feet (USGS 1981, Donohue & Associates 1990a, Donohue & Associates 1991c).

Soil Type

The principal soils on site are the Tawas Muck (present in the center to southeastern quadrant of the Site) and the Plainfield Fine Sand (present in the northeast quadrant and south central area of the site). The Tawas Muck is a poorly drained soil with rapid permeability, high organic matter content and high available water for plant growth. The Plainfield Fine Sand is a rapidly drained, highly permeable sand with a high content of organic matter and low available water for plant growth (SEC Donohue 1992).

Other soils on site include the Tyner Loamy Sand, the Gilford Sandy Loam and the Oshtemo Loamy Sand. The sands are somewhat excessively drained with rapid permeability and low available water for plant growth. The loam is very poorly drained with rapid permeability and has moderate available water for plant growth (USDA 1989).

Surface Water Hydrogeology

The site is located in the St. Joseph River basin. The river is approximately two miles south of the site. The St. Joseph River flows east to west ultimately into Lake Michigan at St. Joseph, Michigan.

A portion of the site was originally a marsh that has been filled with various wastes (Donohue & Associates 1990a). Three surface water bodies have been excavated on site and have been likely filled by precipitation, surface runoff and possibly, groundwater discharge.

A surface water runoff analysis determined that the site has two primary drainage areas, which divide the site in approximately two halves from northwest to southeast (Donohue & Associates 1991a). The approximate eastern section of the site drains to the quarry pit pond and the approximate western section of the site drains to the other two ponds and off site to the west and to a lesser extent, to the northwest. The ponds on the western section of the site would overtop in a 100-year flood event and flow to the west.

Description of Surface Water Bodies

The largest surface water body is the quarry pit pond located in the northeast corner of the site. It is approximately 550 by 850 feet. The shoreline and bottom are generally sand and gravel. The larger of the other two ponds is "L"-shaped with the longer channel oriented north-south and the shorter channel oriented east- west. Each channel is approximately 100 feet wide and

400 feet long. The smallest of the three surface water bodies is located directly northeast of the "L"-shaped pond and is approximately 100 by 170 feet. The shorelines and bottoms of the two smaller ponds are sand and gravel (Donohue & Associates 1991d). Within a one-mile radius of the site, located directly south of the site, are four additional quarry pit ponds.

Groundwater Hydrogeology

Groundwater flow is generally southeast toward the St. Joseph River which is a regional discharge. The saturated zone has a high hydraulic conductivity with a low vertical and horizontal gradient, implying that pumping of wells would have a significant effect on the groundwater (and contaminant) flow direction. Deep pumping would increase the vertical gradient, thereby causing the groundwater (and contaminants) to migrate downward. Groundwater occurs between 5 and 20 feet below the site at elevations from 752 to 756 mean sea level (MSL) within the sand and gravel outwash deposits. (The elevation of the waste mass is 755 to 760 feet MSL.) The aquifer is unconfined below the site and the approximate saturated thickness of the aquifer ranges from 40 to 450 feet in the region (Donohue & Associates 1990b, 1991c, 1991e).

Virtually all residences and businesses south of the Himco Dump are connected to the municipal water supply. There is one residence at 28498 County Road 10 (south and west of the site) where a drinking water well is presently in use. This well was sampled in May 1992 and no contamination was detected (Steadman 1992). It would appear that this well is too far west to be considered downgradient. The municipal well field is located approximately a mile and a half south of the site (Main Street Well Field). Residences and businesses east and southeast of the site utilize private water wells.

Vegetation

The amount and composition of the vegetation varies across the site. Two known barren areas of sand and/or calcium sulfate exist south of the quarry pit pond and north of the lower channel of the "L"-shaped pond. A mixed deciduous and nondeciduous forest surrounds the quarry pit pond and the remainder of the site is a mix of grass, low vegetation, shrubs and trees. In the past, soybeans were grown on the western half of the site. Additional details on site vegetation are included in the Environmental Evaluation prepared for the site (Life Systems 1992).

Wetlands

The only wetland on site is located directly south of the east portion of the quarry pit pond. The wetland is approximately 2,500 square feet in size (less than one-half acre). The areas surrounding the other surface water bodies (and sampled as suspected wetland areas) are not considered jurisdictional wetlands nor what would be typically considered "wetlands" as defined by current wetland description criteria (Donohue & Associates 1991g). The soil, vegetation and hydrogeology of the areas are not characteristic of wetlands.

3.1.2 Potentially Exposed Populations

Current Populations/Land Uses

The city of Elkhart has a population of 43,627 (USDC 1990) and covers approximately 17 square miles. Within a one-mile radius there are a variety of land uses, including residential, commercial, industrial and agricultural. At one time approximately one-third of the site was used for soybean production.

No one currently resides or works on the site. However, on-site visitors have been observed engaging in recreational activities such as hunting and dirt-bike riding[a,b]. Other similar activities could potentially include playing, walking, fishing, wading and swimming.

There are residences near the site (east, west, south and southeast) and industrial and commercial properties southeast of the site (Figure 1-2). The residences located east of the site are downwind and side-gradient (with respect to groundwater flow); residents and workers south of the site are upwind and downgradient.

Future Populations/Land Uses

Several hypothetical future land uses are possible, but may not be technically and/or financially reasonable. Possible future scenarios include development of residences or commercial/industrial properties on site. The composition of the natural soils in combination with the shallow water table and fill material would make construction on the site difficult and potentially costly. Construction along the perimeter of the site (not on the landfill) would be more feasible. Other hypothetical future land uses include both recreational or agricultural. The site could revert back to cropland (e.g., a soybean field) or be developed as for outdoor recreational activities (e.g., a park). Therefore, hypothetical future on-site populations could include residents, industrial workers, agricultural workers and recreational populations.

If development is limited or does not occur, it is anticipated that future recreational activities would be similar to current recreational activities.

3.1.3 Potentially Sensitive Subpopulations

Sensitive subpopulations are groups or individuals who may be more sensitive to chemical exposures in general because of their age or health status (USEPA 1989a). No groups of specific sensitive subpopulations (e.g., nursing homes, hospitals, schools) are located near the site.

(a) Personal conversation between Marcia Kuehl and Donna Studniarz, May 9, 1991.
(b) Personal conversation between Steve Padovani and Donna Studniarz, May 9, 1991.

3.2 Identification and Analysis of Complete Exposure Pathways

An exposure pathway describes the movement of a chemical from a source to the point where an individual comes in contact with that chemical. A complete exposure pathway consists of the following:

- A source and mechanism of chemical release
- A transport medium
- A point of potential contact with the contaminated medium
- An exposure route at the contact point
- A potentially exposed population

A complete pathway generally contains all these elements. In some instances, the source is also an exposure point and there is no release or transport involved. If a pathway is not complete, there is no exposure and therefore risk cannot be characterized.

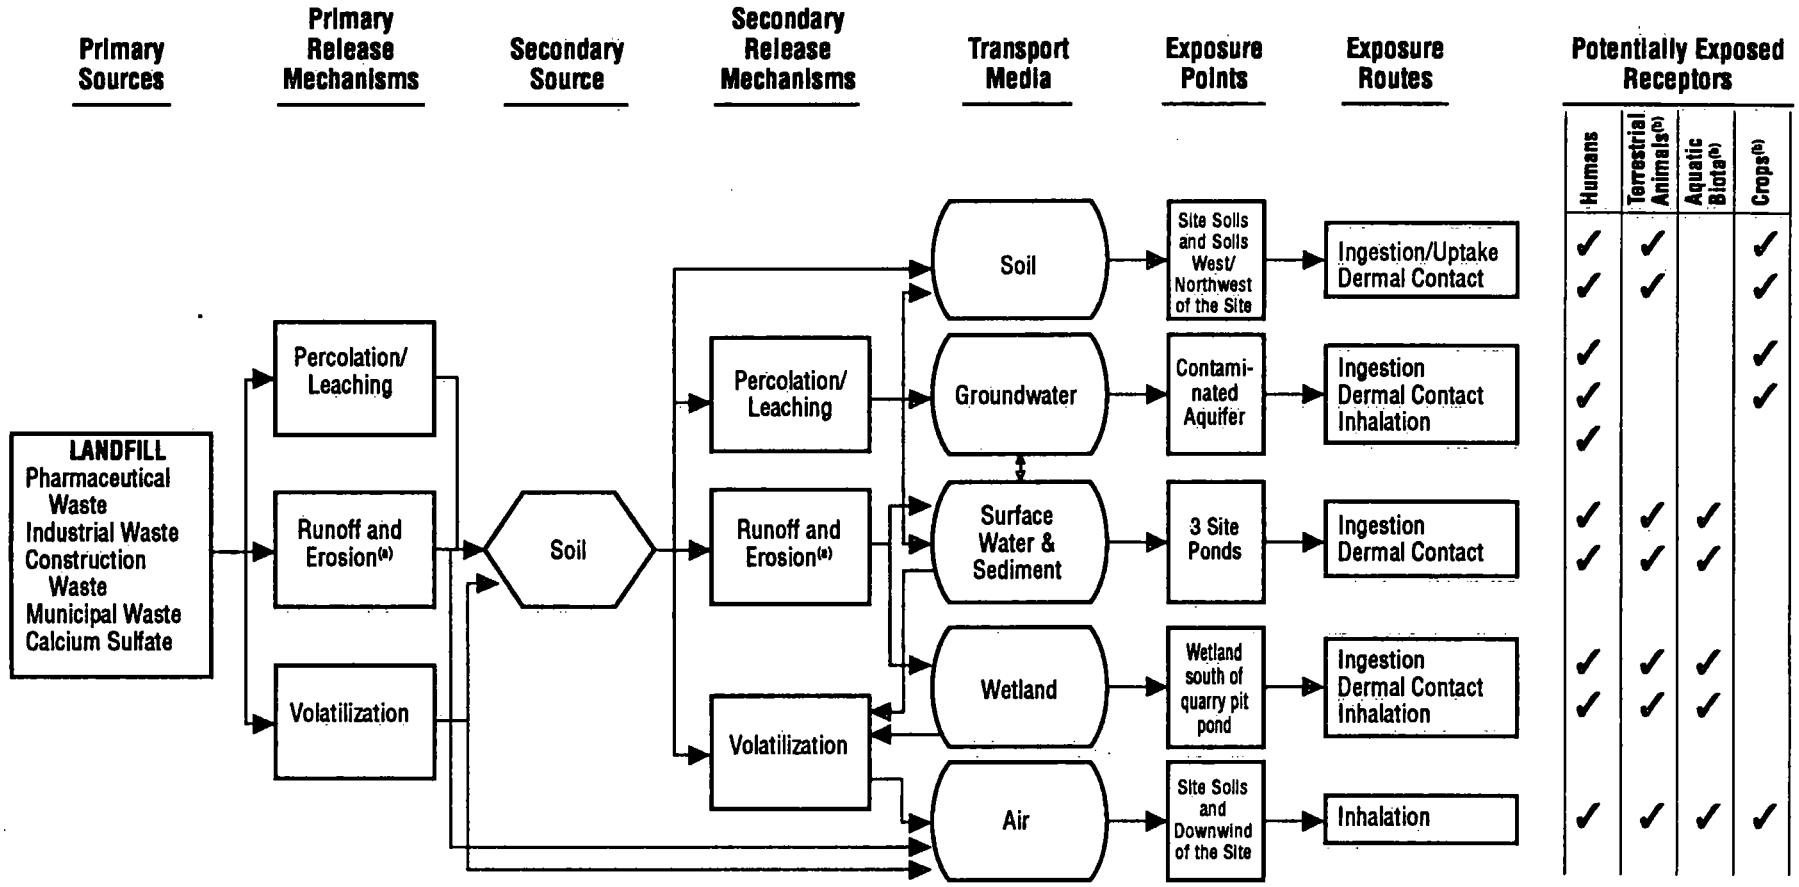
The information available for the Himco Dump site was evaluated to determine which exposure pathways are complete. To illustrate the exposure pathways from sources to receptors, a conceptual site model was developed and is illustrated in Figure 3-1. The elements of this model are described in more detail below. All possible and reasonable exposure pathways are first identified and evaluated for completeness and exposure pathways are then selected for quantification.

Identifying complete exposure pathways involves not only characterizing site features but must also take into consideration physical and chemical properties of the site contaminants. Predicting the fate and transport of all the chemicals of potential concern from their source at Himco to receptors at an exposure point is difficult on a chemical-by-chemical basis. However, some assumptions can be made by assuming classes of similar compounds behave similarly. More detailed information on site fate and transport is included in the RI Report (SEC Donohue Inc. 1992). This information has been taken into consideration in the following pathway analyses.

3.2.1 Identification of Exposure Pathways

Sources, Release Mechanisms and Transport Media

The Himco Dump is an uncontrolled landfill without a liner or recovery systems for leachate or gas. The wastes were landfilled directly on to the ground surface across the site and in trenches. Reportedly, paper wastes were dumped and burned in the trenches. The landfilled area was covered on a regular basis with sandy soil from the quarry pit, excavated ponds and any source around the site perimeter. Wastes consisted primarily of calcium sulfate sludge and to a lesser extent, pharmaceutical, industrial, construction and municipal wastes. When the landfill closed in 1976, a cover of calcium sulfate and sand was laid over the wastes. These landfilled wastes are the primary sources of contamination. Once buried, wastes can travel through the vadose zone to groundwater (via percolation) or volatilize into the atmosphere.



(a) Includes wind erosion and mechanical (e.g. vehicular) erosion.
(b) Terrestrial animals, aquatic biota and crops may be secondary or tertiary sources for human receptors.

FIGURE 3-1 CONCEPTUAL SITE MODEL

Percolation, leaching, runoff and erosion are all possible transport mechanisms. The rate of this transport is dependent on groundwater velocity as well as the properties of the chemicals themselves (solubility, dispersity, adsorption, etc.). Nearly every chemical detected in soil was also detected in groundwater or leachate water. Concentrations of volatiles in soil generally increase with depth. The highest concentrations are in subsurface soil followed by groundwater. Although this pattern is not consistent with the inorganics, all inorganics detected in soil were detected in groundwater (with the exception of cyanide). Thus, the data generally support the movement of wastes to the groundwater.

The sand and calcium sulfate cover is insufficient to prevent migration of contaminants. The cover is also not consistently thick enough (it thins west to east and is nonexistent in some areas) to prevent potential migration of volatile contaminants or fugitive dust emissions (from wind or mechanical/ vehicular erosion) to the atmosphere (Donohue & Associates 1991h).

The contaminants in groundwater were detected in both shallow and deep wells, indicating an unconfined aquifer (SEC Donohue 1992). The contaminants appear to be diluted by recharge events and have moved into the aquifer (Donohue & Associates 1991c). Currently, residences immediately south of the site are all on city water. There is one drinking water well in use located south of County Road 10. This residence appears to be far enough west of the site to be unaffected by off-site contaminant migration. Residents east of the site are located outside of the city limits and do draw from the aquifer. Groundwater drawn from these wells was determined to be unaffected by site contaminants (Donohue & Associates 1991b).

The USGS identified a bromide plume originating from the site and migrating away from the site in a south-southeasterly direction (Appendix E, Donohue & Associates 1990a). The plume had extended less than a mile from the site in USGS studies through 1987 (Donohue & Associates 1990a). The extent of the plume appears constant and the concentrations are gradually decreasing (Donohue & Associates 1990a).

It is unlikely that contaminants will migrate to the Main Street wellfield (the source of drinking water for the city of Elkhart, approximately 1-1/2 miles to the southeast) and if so, would be diluted by a factor of 10^6.[(a)] Based on the above information, it is unlikely significant levels of contaminants would migrate to the St. Joseph River.

Surface soil and subsoil are secondary sources of contaminants. An important intermedia transfer mechanism is percolation of precipitation and contaminant leaching, which can lead to transport of contaminants from soil to groundwater to surface water bodies and the wetland area. Contaminants in soil can also impact the three surface water bodies and the wetland area by erosion and surface runoff (Donohue & Associates 1991a). The data however, do not clearly support the transport of soil contamination to the surface water.

(a) Personal conversation between Vanessa Harris and Donna Studniarz, June 25, 1991.

Leachate water was observed and sampled from several test pits. This leachate water was primarily found at elevations above the water table and is suspected to be from perched locations within the landfill waste (SEC Donohue Inc. 1992). The RI also concluded that groundwater is in contact with the waste. Contaminants detected in leachate waste may, therefore, be a source of groundwater contamination.

Contaminants in soil, surface water, sediment and the wetland area could also potentially bioaccumulate in aquatic biota (e.g., fish) or be ingested by terrestrial animals, which would become secondary or tertiary sources of contaminants. Bioaccumulation can be predicted by evaluating a chemical's water solubility and octanol water partition coefficient (K_{ow}). Chemicals that are highly soluble (>1,000 ppm) with a K_{ow} <500 are considered negligible bioaccumulators (Ney 1990). Of the organic chemicals detected in surface water, only ethylbenzene would be expected to bioaccumulate, but it is not considered a strong bioaccumulator.

Crops grown on or off site could potentially be affected by site contaminants via irrigation with groundwater contaminated by the site.

Exposure Points

An exposure point is defined as that point where a human can come in contact with a contaminated medium. The contaminated source, transport medium or release point itself can also be an exposure point (e.g., contaminated surface soil). Current exposure points identified for the Himco Dump site include:

- On-site surface soil
- Surface water and sediments in/around the quarry pit pond, the "L"-shaped pond and the other small pond
- Wells south of the site
- Surface soil west and northwest of the site
- Residences located downwind of the site (northeast)

Additional hypothetical future exposure points include:

- Site subsoil
- Hypothetical well drilled on site
- Hypothetical well impacted by site contaminants drilled southeast of the site

Exposure Routes

Human populations may be exposed to contaminants by the following three routes: (1) ingestion of contaminated media, (2) inhalation of contaminated media and (3) dermal contact with contaminated media.

Based on the nature of contamination and the anticipated activities at the exposure points, exposure routes identified as likely at the Himco Dump site include the following:

- Ingestion and dermal contact with soils
- Ingestion and dermal contact with groundwater
- Inhalation of volatiles released from groundwater uses within a home
- Ingestion and dermal contact with surface waters and sediments
- Inhalation of volatile and/or particulate emissions from site soils, surface water and sediments
- Ingestion of contaminated crops or animals (e.g., aquatic or terrestrial)

3.2.2 Complete Exposure Pathway Analysis

The exposure pathways judged complete for current and hypothetical future land uses are listed in Tables 3-1 and 3-2. Potential pathways that are judged to be incomplete (e.g., no exposure point and/or route by which contact could occur) are not quantified. From all the complete exposure pathways at the site, some pathways were eliminated for quantitative analysis based on one or more of the following reasons:

- The exposure resulting from the pathway is judged likely to be substantially less than that from another pathway involving the same population and the same medium (e.g., inhalation of particulates while walking on site compared to inhalation of particulates while dirt-bike riding on site).
- The potential magnitude of exposure to a population is considerably less than that of another population by a similar pathway (e.g., exposure of upwind residents to airborne particulates is substantially less than exposure to downwind residents via the same pathway).
- The probability of the exposure occurring is very low. For example, ingestion of fish is considered a pathway of low exposure potential since both the contaminant levels are low and the associated exposure duration and frequency are very low.
- The necessary data to quantify a pathway are not available and cannot be reliably estimated (e.g., concentration of contaminants in crops).

The justifications for not quantifying pathways are summarized in Tables 3-1 and 3-2. More detail on several of these rationales is provided below.

TABLE 3-1 POTENTIALLY COMPLETE EXPOSURE PATHWAY SUMMARY - CURRENT LAND USE

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Residents in homes immediately south of the site	Ingestion of groundwater from a well downgradient of site, inhalation of volatiles released from groundwater into household or dermal exposure to groundwater during showering or bathing	No	Residents immediately south of the landfill are currently on city water, although there is no prohibition against use of these drinking water wells.
	Inhalation of volatiles or contaminated airborne particulates from the site	No	Residence is upwind and exposure is likely to be less than a downwind resident.
	Visiting the site to dirt-bike, walk, fish, swim or hunt may result in potential exposure to site contaminants via ingestion and direct contact with soils, surface water, sediments and consumption of contaminated fish and terrestrial animals	No	A separate recreational population is evaluated. These residents assumed to have similar or lower exposures.
Residents east/north east of the site	Inhalation of contaminated airborne particulates from the site	Yes	Residences are downwind of the site
	On-site recreational exposure scenarios (described above for the residents south of the site)	No	A separate on-site recreational population is evaluated. These residents assumed to have similar or lower exposures.

continued-

Table 3-1 - continued

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Residents west/north west of the site	On-site recreational scenarios (described above)	No	A separate recreational population is evaluated. These residents assumed to have similar or lower exposures
Recreational visitors on site	Visitors on site are assumed to engage in recreational activities potentially resulting in the following exposures:		
	• Inhalation of airborne particulates while dirt-bike riding on site	Yes	Dirt-bike riding has been observed on site
	• Inhalation of volatiles while dirt-bike riding on site	Yes	Dirt-bike riding has been observed on site
	• Ingestion of soil while dirt-bike riding on site	Yes	Dirt-bike riding has been observed on site
	• Ingestion of surface water and sediment while fishing or wading in site ponds	Yes	Children may ingest surface water and sediment while fishing and wading in ponds on site
	• Dermal contact with surface water	Yes	Children may contact surface water while fishing and wading in ponds on site

continued-

Table 3-1 - continued

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Recreational visitor (continued)	• Dermal contact with sediments	No	Cannot be reliably estimated.
	• Consumption of fish caught in a pond on site	No	Detected chemicals not strong bioaccumulators, fish supply not large enough to be considered a reasonable food source. (see text)
	• Consumption of animal meat (i.e., deer) from hunting on site	No	Unable to quantify reasonably with available data.
	• Other exposure pathways from potential recreational activities (i.e., inhalation of particulates while walking, ingestion of dirt while picnicking, etc.)	No	The potential magnitude of these exposures is considerably less than that from the above exposures via the same routes.

TABLE 3-2 POTENTIALLY COMPLETE EXPOSURE PATHWAY SUMMARY - FUTURE LAND USES

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Residents on site	Ingestion of contaminated soil while playing or gardening	Yes	Residential development of the site is possible, more probably along the perimeter in the south-eastern section of the site. Residence on landfill itself not as likely, but nonetheless also evaluated.
	Inhalation of contaminated particulates via mechanical or wind erosion from soil	Yes	Pathway complete if development occurs on landfill area.
	Inhalation of volatiles from soil	Yes	Pathway complete if development occurs on landfill area.
	Inhalation of landfill gases	No	Even if development occurred on site, construction of a house with a basement is extremely unlikely. Data not available to quantify pathway.
	Consumption of produce grown on site	No	Unable to quantify with available data (see text).

continued-

Table 3-2 - continued

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Residents on site (continued)	Ingestion of contaminated surface water and sediment while fishing or wading in surface water bodies on site and inhalation of contaminated particulates and ingestion of surface soil from dirt-bike riding	No	Exposure is assumed to be similar to a current recreational visitor.
	Ingestion of groundwater from a well drilled on site, inhalation of volatiles released from groundwater into household air, dermal exposure to groundwater during bathing or showering	Yes	It is assumed residents may drill a drinking water well on site.
	Other exposure pathways (i.e., ingestion of particulates while walking, ingestion of soil while bicycling, etc.)	No	Magnitude of exposure is low in comparision to above pathways via the same exposure route.
Occupational Workers on site	Ingestion of contaminated soil	Yes	Reasonable potential exposure, although commercial development more likely south of the landfill rather than on the landfill area itself.
	Inhalation of volatiles and contaminated particulates from soil	Yes	Same as above
	Ingestion of groundwater from well drilled on site	Yes	Assumption that the facility may drill a drinking water well is reasonable.

-continued-

Table 3-2 - continued

Potentially Exposed Population	Exposure Route, Medium and Exposure Point	Pathway Selected for Quantitative Evaluation?	Reason for Selection or Exclusion
Agricultural Workers on site	Ingestion of contaminated soil	Yes	Future agricultural use possible, exposure frequency and potential could be significant.
	Inhalation of volatiles from soil and contaminated particulates from wind or mechanical erosion	Yes	Exposure to volatiles and airborne particulates is possible while working in the field.
	Ingestion of groundwater from well drilled on site	Yes	It is assumed drinking water may be from a well drilled on site.
Recreational visitor	Exposure routes, media and exposure points similar to those described for a current recreational visitor	No	Exposure assumed to be similar to current recreational visitor.
Off-site resident north/northeast of the site	Inhalation of volatiles and contaminated particulates from the site assuming agricultural development	Yes	Reversion to agricultural use possible.
	All other potential exposure pathways	No	Exposure frequency and duration would be similar or lower than for other populations with the same exposure routes.

Ingestion of Crops. A portion of the site has previously been used for crops and nearby residents do have vegetable gardens.[a] However, quantifying this pathway would require considerable data that are not available: concentrations of contaminants in garden soil (considering any additions of soil enhancers or fertilizers), types and quantities of vegetables grown, quantitative estimates of uptake of contaminants by those vegetables and quantitative estimates of the amount of home-grown or site-grown produce consumed by an individual. Therefore, this pathway was not quantified. The uncertainty contributed by the lack of quantification of this pathway is discussed further in Section 6.0 of this report.

Ingestion of Fish

Although there is evidence that fishing occurs at the three surface-water bodies it is not certain that any fish caught are actually consumed. The ponds are not large enough to produce a consistent supply of edible-size fish that would be a reliable food source. Therefore, this pathway was not quantified.

Dermal Contact with Soil or Sediments

Dermal contact with soil or sediments could be a route of exposure at this site. However, quantification of dermal exposure via soil contact is extremely uncertain due to lack of data on the rate of chemical absorption from soil across the skin (USEPA 1992a). Therefore this pathway was not quantified.

Table 3-3 summarizes the pathways selected for quantitation.

3.3 Quantification of Exposure

The magnitude of human exposures to chemicals is usually expressed in terms of the average daily intake (DI), which is the amount of chemical in contact with a body exchange surface (skin, lungs, gastrointestinal track). To calculate intakes, the following general equation is used:

$$I = C \times \frac{CR \times EFD}{BW} \times \frac{1}{AT} \qquad (1)$$

where:

- I = Intake; the average amount of the chemical at the body's exchange boundary (mg/kg-day).
- C = Chemical concentration; the average concentration which comes in contact with the body during the exposure period at the exposure point (mg chemical/unit of environmental medium).
- CR = Contact Rate; the amount of contaminated medium contacted per unit time or event (e.g., L/day for drinking water).

(a) Observation by Life Systems, Inc. personnel Jo Ann Duchene and Michael Kangas during a site visit in October 1990.

TABLE 3-3 SUMMARY OF EXPOSURE PATHWAYS SELECTED FOR QUANTIFICATION

Land Use	Potentially Exposed Population	Exposure Point	Exposure Medium	Exposure Route
Current	Dirt-bike rider	Site	Soil	Ingestion Inhalation
			Air	- Particulates - VOCs
	Wader	Surface water on site (ponds or quarry pit)	Surface water	Ingestion Dermal contact
			Sediment	Ingestion
	Residents (child and adult) northeast of site	Closest downwind residence northeast of site	Air	Inhalation - Particulates - VOCs
Hypothetical Future	Residents (child and adult)	Residence on landfill or south of landfill area	Soil	Ingestion Ingestion
			Groundwater	Inhalation-VOCs Dermal
	Workers	Plant or office facility on landfill or south of landfill area	Soil Groundwater	Ingestion Ingestion
	Agricultural Workers	On landfill area	Soil	Ingestion Inhalation
			Air	- Particulates - VOCs
			Groundwater	Ingestion
	Residents (child and adult) northeast of site	Closest downwind residence northeast of site (assuming future agricultural development)	Air	Inhalation - Particulates - VOCs

EFD = Exposure Frequency and Duration (how long and how often exposure occurs). The EFD term is usually calculated using two terms, the exposure frequency (EF) (usually expressed days/year) and exposure duration (ED) (usually expressed in years).

BW = Body Weight; the average body weight over the exposure period (kg).

AT = Averaging Time; period over which exposure is averaged (days).

In general, the values of C and the remaining exposure factors can depend on time. Therefore, it is necessary to calculate intakes for subchronic (14 days to 7 years), chronic (7 years or more) or lifetime (70 years) exposure periods.

The variables in this equation are chosen so that an estimate of the reasonable maximum exposure (RME) for each pathway is achieved (USEPA 1991c, USEPA 1989a). The RME is defined as the maximum exposure that is reasonably expected to occur (USEPA 1989a).

This step is undertaken in two stages: estimation of exposure concentrations (the "C" term in the equation) and calculation of human intake factors (HIFs) (the "CR," "EFD," "BW" and "AT" terms).

3.3.1 Estimation of Exposure Point Concentrations

An exposure point concentration is the arithmetic mean concentration of a chemical in a medium, averaged over the area within which exposure is expected to occur (USEPA 1989a). Although this concentration is usually not the maximum concentration that could potentially be contacted at any one time, it is regarded as a reasonable estimate of the concentration that is likely to be contacted over time. Because of the uncertainty associated with estimating the true arithmetic mean from a limited number of samples, a degree of conservatism is needed in calculating exposure point concentrations (USEPA 1989a). This conservatism is provided by using the upper 95th confidence limit of the arithmetic mean (AM_{95}).

The concentration of a chemical in the environment may not be constant over time, but may tend to decrease due to volatilization, degradation or migration. When data permit, it is therefore advisable to obtain concentrations of the chemicals of concern to allow for time trends. At the Himco site there is no available quantitative information regarding this, therefore, concentration values are assumed to remain constant over the next thirty years (the maximum exposure duration evaluated).

Calculation of exposure point concentrations is sometimes complicated by the presence of nondetects in the data set, the small number of data points at a given exposure point or large variation among sample results. In calculating exposure point concentrations for this site, the following rules were employed:

- If a chemical was not detected in any of the samples used for the exposure point concentration calculation, it was assumed to be absent (i.e., the exposure point concentration was taken to be zero). There were several exceptions to this rule as detailed below.

- If a chemical was detected in soil anywhere on site, but not detected in any groundwater sample, the AM_{95} was calculated using one-half the detection limit. This reflects the assumption that the soil serves as a source of contamination to the groundwater.

- If a polycyclic aromatic hydrocarbon (PAH) was detected only in soil it was assumed to be absent (at zero) in any groundwater exposure point concentration calculation. This reflected the assumption that PAHs in general are not mobile and are not expected to migrate from soil to groundwater.

- If a chemical was detected in at least one groundwater sample but not within the particular wells selected to represent a given exposure point, the AM_{95} was calculated assuming this chemical was present at one-half the detection limit.

- In any data set for a given exposure point if a chemical was detected at least once, the nondetects for that chemical were evaluated at one-half the reported detection limit.

- If the AM_{95} in any calculation exceeded the highest detected value, then the maximum detected value, rather than the AM_{95} was used as the exposure point concentration.

Calculations of exposure point concentration for each medium are detailed below.

Groundwater

For all hypothetical future site development, it is assumed that a well is drilled on site either through the waste mass of the landfill or in the southeastern section of the site. In accordance with guidance (USEPA 1991a, USEPA 1989a), the exposure point should be selected to represent the center of the contaminant plume. There does not appear to be a well defined plume. Therefore, the exposure point concentration for future hypothetical groundwater within the waste mass was approximated by using the leachate water samples (with the exception of TL-05) and the wells located on the perimeter of the waste mass. The leachate waste sample from TL-05 was a biphasic sample containing almost 50% toluene and a variety of other volatile organic compounds. This sampling area was the location of the removal activity which occurred in May 1992. Therefore, sample TL-05 was not used since it is not representative of the aquifer quality. Use of this sample in an AM_{95} calculation would result in a skewed exposure point concentration, which would be extremely unreasonable.

To approximate the contaminant concentration in the area south of the landfill, wells in that area were used. Wells further down gradient or side gradient were excluded. For these residential scenarios shallow and deep wells were evaluated separately. If the site were commercially developed a shallow well was judged to be insufficient, therefore, only a deep well was evaluated for a future commercial land use.

Surface Water and Sediment

The wader is assumed to fish and play/wade on site either by the quarry pit pond or the two smaller ponds in the southwestern section of the site. Therefore, the exposure point concentrations for exposure to the quarry pit pond include all surface water and sediment samples in the quarry pit pond and for exposure to the two smaller ponds, all surface water and sediment samples associated with the two smaller ponds.

Soil

Two future hypothetical residential/commercial development exposure points were evaluated. It is extremely unlikely that construction of a house or commercial plant would occur on the waste mass (landfilled) areas of the site due to structural and economic considerations. Nonetheless, this exposure point was evaluated utilizing surface soil samples taken from the landfill cap. Development would more likely occur south of the landfilled area. This assumption is supported by the presence of residences just off site to the west and east. The exposure point concentration for this scenario utilized soil samples taken this area. The hypothetical future agricultural scenario was quantified assuming the landfilled area would revert to crops.

The dirt bike riders were assumed (and observed) to ride in general across the landfilled area and just south of it. The samples used in the exposure point calculation utilized surficial soil samples from the landfill area, the dirt bike trail just south of the quarry and samples just south of the landfill border area.

Air

In order to quantify the air pathway, the following procedures were used for particulates and volatiles.

The concentration in air of a specific chemical of potential concern that is present in respirable particulate matter (PM_{10}, particulate matter less than 10 μm in diameter) in air is calculated from the concentration in soil as follows:

$$C_{(air)}(mg/m^3\ air) = C_{(soil)}(mg/kg) \times PM_{10}\ (kg/m^3) \qquad (2)$$

Appendix 2 describes the estimation of PM_{10} concentrations for each exposure point evaluated using emission and transport modeling. These values were then used in Equation 2 along with the values of exposure point concentrations in soil to calculate contaminant concentrations in air.

No monitoring data were available to indicate the concentrations of volatiles in air due to release at the site. Therefore, a soil volatilization model and a box model were used to calculate the average concentrations that would be

expected, based on the measured levels in soil. The volatilization model chosen was Hwang (1986) as suggested by USEPA (1988a). A detailed description of the Hwang model, box model and all input parameters employed is presented in Appendix 3.

Samples used in calculations of exposure point concentrations are summarized in Table 3-4. Worksheets documenting exposure point concentrations are included in Appendix 4.

3.3.2 Calculation of Human Intake Factors

In the general equation for calculating intake (Equation 1), the HIF incorporates the terms that describe exposure in terms of human activity. The value of the HIF term in calculating chemical intakes depends on the specific exposure scenario being evaluated. An HIF value is calculated individually for each exposed population, for each medium, for each exposure route and for each exposure duration. In general, an HIF value is comprised of three terms:

- A contact rate term that describes the amount of intake of a medium (e.g., mg of soil or L of water) by a person on a day when exposure occurs.
- A body weight term.
- A series of time correction factors that account for the fact that exposure may not occur every day during the time period of interest. These variables include exposure time (hours/day), exposure frequency (days/year) and exposure duration (years). These factors are divided by the period (in days) over which exposure is averaged (averaging time).

Activity Patterns of Potentially Exposed Populations

Human intake factors are derived for all assumed populations (Table 3-3). A brief description of the assumed activity patterns of these populations is presented below.

Hypothetical Future On-Site Residents. A maximally exposed adult resident would be an adult who works at home, is retired or unemployed. A child is maximally exposed during the ages at which contact with contaminated media is greatest and when time at home is greatest. Therefore, a child aged one to six years is evaluated. The resident assumed to live in a home constructed on site (either on the landfill or south of it) and drink from a well drilled near their home.

Current Off-Site Downwind Resident. These individuals represent child and adult residents who are exposed to airborne site contaminants via volatiles and wind and mechanical (dirt-bike riding) erosion. The maximally exposed individuals would be a full-time adult resident and a child resident aged one to six years.

TABLE 3-4 SUMMARY OF MONITORING DATA USED IN CALCULATING EXPOSURE POINT CONCENTRATIONS

Exposure Point	Samples Used[a]
Current Land Use Scenarios:	
Site area utilized for dirt-bike riding; Off-site residence (downwind)	WS-03 to WS-06, WS-10 to WS-12, WS-14, WS-15, GS-01 to GS-12, HS-03 to 07, HS-09
Site surface water bodies and sediment (quarry pit pond)	SS-09 to SS-12, SS-16 to 18 and SD-09 to SD-12, SD-16 to SD-18
Site surface water bodies and sediment (2 smaller ponds)	SS-01 to SS-08, SS-13 to SS-15, SD-01 to SD-08 and SD-13 to SD-15
Hypothetical Future Land Use Scenarios:	
On-site residence or plant south of landfill - soil	WS-13 to 16, HS-06 to HS-09, TL-3DS1
- groundwater	
- shallow well[b]	WTE-2, WTM-2, WT-101A, WT-111A
- deep well	WTE-3, WTM-1, WT-101B, WT-101C
On-site residence/ plant/cropland on landfill - soil	WS-03 to WS-06, WS-10 to WS-12, GS-01 to GS-12
- groundwater	TL-1, TL-2, TL-4, WTCP-1, WT-103A
Off-site residence (downwind)	WS-03 to WS-06, WS-10 to WS-12, WS-14, WS-15, GS-01 to GS-12, HS-03 to HS-05

(a) All associated field duplicate samples were averaged prior to the calculation of exposure point concentrations.
(b) Residence only.

Future Off-Site Residents - Downwind. These residents (adult and a one- to six-year-old child) are assumed to be the maximally exposed individuals located downwind (northeast) of the site who inhale volatiles and airborne particulates from wind and mechanical (plowing) erosion from the site assuming it is developed as agricultural land. These populations differ from the current off-site downwind resident only in their additional exposure to dust generated via agricultural activities.

Current Dirt-Bike Rider. This individual represents a young adult who may visit the site for the purposes of dirt-bike riding. For the purposes of evaluating a maximally exposed individual over a lifetime, it is assumed the dirt-bike rider is an adult male over the age of 18 years. It is possible that older children (e.g., ages 12 to 18) would participate in this type of activity. Although this individuals' dose could be slightly higher than an adult (since they weigh less), their exposure duration would also be less (six years). Therefore, an adult represents the maximally exposed individual for this activity.

Current Wader. It is assumed that a younger individual (aged 12 to 18 years) rather than an adult would be more likely to fish, play or wade in the three surface water bodies. It is assumed this older child may go fishing either in the quarry pit pond or the two smaller ponds and play or wade along the edges of these ponds. For the purposes of this assessment, this individual will be referred to as the "wader."

Hypothetical Future On-Site Plant Workers. These individuals are assumed to be adults who could work at a plant or facility constructed in the same section of the site as a hypothetical residence (either on the landfill or just south of it). It is assumed the work is indoors and does not entail significant outdoor labor and that drinking water is available from a well drilled near the building.

Hypothetical Future On-Site Agricultural Workers. These adults are assumed to work on site assuming the site is developed as a field of crops (such as soybeans or corn). It is assumed an agricultural worker works in the field plowing/tilling in the spring and performs related operations occasionally during the growing season (May to September). Exposures to particulates only occurs during those plowing/tilling activities that generate dust. It is also assumed the worker has access to drinking water during his workday from an on-site drinking water well.

Quantitative Evaluations

The following values are used in the pathway-specific exposure calculations unless otherwise specified in the individual exposure scenarios described below.

Body Weight. An average human body weight of 70 kg (154 lb) is assumed for adults (residents, plant and agricultural workers and dirt-bike rider). An average body weight of 15 kg (33 lb) is assumed for children aged one to six years (resident) (USEPA 1991c). An average body weight of 56 kg (123 lb) is assumed for the 12-to 18-year-old wader (USEPA 1989b).

Exposure Frequency. Residential exposure frequency is based on full-time residence, with 15 days per year spent away from home, resulting in a residential exposure frequency of 350 days per year (USEPA 1991c). This frequency is assumed for all residential exposures.

For agricultural workers, exposure is assumed to occur during the spring and occasionally during the growing season (May through September). It is assumed these workers work a total of 20 days/year. Ten of these 20 days are assumed to involve plowing/tilling operations.

Occupational exposure frequency is assumed to be five days per week and to occur year-round except for a two-week vacation, resulting in an exposure of 250 days per year (USEPA 1991c).

Frequency of exposure for recreational populations is uncertain. For the dirt-bike rider, it is assumed a reasonable maximum exposure would be two days a week on site during the non-winter months (e.g., nine months per year) of the year or 39 weeks per year, for a total of 78 days per year. It is suspected that any dirt-bike riding which may occur during the winter months (i.e., during a warm spell) would be balanced by periods during the summer months that riding would be unlikely to occur (i.e., periods of heavy rains, vacations away from home). For the wader, it is assumed a reasonable maximum exposure would be two days per week during the non-school months of the year (approximately three months from mid-June to Labor Day) or 11 weeks per year, for a total of 22 days per year.

Exposure Duration. Residents typically live in a single home for an average of 9 years and up to a reasonable maximum of 30 years (USEPA 1991c). Based on this, exposure duration of adult residents is assumed to be 30 years. Exposure duration for a child resident is assumed to be six years. Workers typically stay at a single job for 25 years or less based on a Bureau of Labor Statistics data (USEPA 1991c), and an exposure duration of 25 years is therefore assumed for the plant worker. No data exist to determine the average length of employment for an agricultural worker, therefore, 25 years is also assumed for the agricultural worker.

The exposure duration for the dirt-bike rider is 30 years, assuming a resident may ride on the site for the period of time he lives near the site. The exposure duration for the wader is six years, the period from 12 to 18 years of age.

Exposure Time. The exposure time for inhalation exposures is 24 hours a day for residents and 8 hours a day for workers (USEPA 1989a). It is further assumed that tilling/plowing are limited to one hour/event. This is the average time to till a field the size of the site. For residential dermal exposures one, ten-minute shower or bath per day is assumed.

There are no available data on exposure times for specific recreational populations, such as dirt-bike riders. Therefore, in the absence of data the exposure time for the dirt-bike rider populations is assumed to be two hours

per week or one hour per event. This is supported by estimates of reasonable average maximum exposures (90th percentile of weighted mean hours per week) (USEPA 1989b) for similar outdoor activities. These estimates range from one to three hours per week.

A reasonable maximum exposure time for a wader is also assumed to be two hours per week, or one hour per event, two events per week. This is assumed based on a study that determined an average of 2 hours per week is spent outdoors by male children aged 12 to 17 years of age while school is open (USEPA 1989b). It is assumed that time spent outdoors would double or triple while out of school, and a portion of this time may be spent wading or swimming in the site ponds. Therefore, it is assumed two hours per week is spent on site wading or swimming in the ponds.

Averaging Time. The averaging time is equal to the exposure duration for subchronic and chronic (noncancer) risks and 70 years for lifetime (cancer) risk (USEPA 1991c).

Contact Rate Terms

Ingestion of Soil. Available data on soil and dust ingestion by humans under typical residential conditions indicate that most soil ingestion occurs by hand-to-mouth activity (cigarette smoking, nail biting, finger wetting, etc.) and during meals (Hawley 1985). For children, mouthing of nonfood items is nearly universal during infancy and decreases with age (Sedman 1989).

For residents, the reasonable maximum soil intake is estimated to be 200 mg per day for children (aged one to six years) and 100 mg per day for adults (USEPA 1991c). These factors account for soil intake of both outdoor soil and indoor dust and are assumed to include episodes of possible increased soil ingestion due to engaging in normal outdoor activities. Thus, an intake of soil and dust of 200 mg/day is assumed for child residents and 100 mg/day is assumed for adult residents. The calculation of HIFs for adult residents is based on a time-weighted equation in which a six-year exposure duration is evaluated at the higher soil ingestion rate (200 mg/day) and lower body weight (15 kg) and a 24-year exposure duration at a lower soil ingestion rate (100 mg/day) and the higher adult body weight (70 kg). All of the ingestion soil is assumed come from site surface soil, i.e., the fractional intake of site soil is 1.0.

For workers, soil intake is highly dependent on the type of activity, and quantitative data on soil ingestion are lacking. Hawley (1985) (USEPA 1991c) estimated adult soil intake of 110 mg/day from cleaning dusty areas and of 480 mg/day from doing yard work for eight hours per day. Calabrese et al. (1990) estimated 50 mg/day for adults who worked outside the home. In the absence of quantitative data, it is assumed that the intake for plant workers is 50 mg/day (USEPA 1991c) and that the activities of the agricultural worker are similar to yard work and therefore the intake is assumed to be 480 mg/day.

For the dirt-bike rider, it is assumed that the intake on site would be considerably higher than an average residential intake, however, the fraction of time (one hour per event) spent on site would limit the intake. In the absence of data, it is assumed that a dirt-bike rider would ingest 50 mg/event of site soils while dirt-bike riding.

Ingestion of Sediments. No data exist on the amount of sediment ingested by children or adults during recreational activities. The 200 mg/day or 50 mg/event soil intake by child residents or dirt-bike riders, respectively, would overestimate an ingestion rate for this type of activity. In the absence of any data, an ingestion rate for sediments is assumed to be 10 mg/event.

Dermal Contact with Surface Water. It is assumed the wader is dressed in a short-sleeved shirt and pants without shoes, which is a total of 4,314 cm^2 of surface area available for contact. However, it is further assumed the wader may go into the water to his knees, thereby also exposing lower legs, resulting in 6,873 cm^2 exposed surface areas exposed to water (USEPA 1989b).

Dermal Contact with Groundwater. It is assumed individuals are totally immersed while showering or bathing. Total skin surface area is assumed as 10,000 and 20,000 cm^2 for children and adults, respectively (USEPA 1989b).

Ingestion of Groundwater. Groundwater is assumed to be the source of drinking water. Reasonable maximum values for ingestion of drinking water are 2 L/day for adults and 1 L/day for children (USEPA 1989b, USEPA 1991c). These values are used for all resident populations. For occupational populations a 1 L/day ingestion rate is used (USEPA 1991c).

Inhalation of Volatiles Released from Groundwater. The presence of volatile contaminants in groundwater leads to inhalation exposure of residents due to release of volatiles to indoor air during household uses of water (use of showers, sinks, washing machines, toilets, dishwashers, etc). The amount of human exposure is a complex function of showering and bathing habits, water temperature and flow rate, whole-house water usage, the size and ventilation characteristics of the bathroom, laundry and house, time spent in each room, and the physical-chemical properties of the contaminants themselves (e.g., Henry's Law constant).

A number of researchers have developed mathematical models to predict air concentration values and/or inhalation doses as a function of the concentration of a contaminant in the water (e.g., McKone 1987, Foster and Chrostowski 1987, Small et al. 1990). As expected, the results vary depending upon the assumptions used in the calculations. Most studies indicate that a reasonable maximum for the inhalation dose ranges from about one-half to five times higher than the ingested dose, with most estimates falling between one and three times the ingestion dose (McKone 1987, Foster and Chrostowski 1987, Small et al. 1990). Since site-specific data are not available to support a detailed evaluation of inhalation exposure to volatiles, a representative exposure level of twice the oral dose has been assumed. Thus the inhaled doses for each resident population are two times the corresponding oral intakes.

Inhalation Rate of Volatiles and Contaminated Particulates. The International Commission on Radiologic Protection determined that a daily inhalation rate of 21 to 23 m^3/day represented an average inhalation rate for male and female adults respectively, engaged in 16 hours at a light activity level (i.e., domestic work, personal care and hobbies) and 8 hours at the rest level (i.e., reading, watching television and sleeping) (USEPA 1991e, USEPA 1989b). More recently, USEPA (USEPA 1991c) has reevaluated the reasonable maximum inhalation rate using activity-specific inhalation rates and specific time-use/activity level data. The conclusion was that 20 m^3/day (0.83 m^3/hr) is representative of a reasonable maximum exposure for adult residents who spend the majority of the day at home. An identical value is assumed for plant workers. The daily inhalation rate of children, however, was not evaluated. In the absence of data, it is assumed a child (up to six years of age) would spend 12 hours a day at a resting level, 8 hours a day at a light level and 4 hours at the moderate activity level (based on time use data (USEPA 1989b)). The following weighting calculation was performed:

Activity Level	Hours/Day	Inhalation Rate, m^3/hr	Time-weighted Inhalation Rate, m^3/day
Resting	12	0.4	4.8
Light	8	0.8	6.4
Moderate	4	2.0	8.0
Heavy	0	2.4	0.0
Total	24	Rate/day:	19.2

Therefore, it is assumed the daily inhalation rate for a child resident is also 20 m^3/day or 0.83 m^3/hr.

The inhalation rate of agricultural workers was calculated in a similar manner. It is assumed agricultural workers are exposed to chemicals volatilizing from soils for a eight-hour work day. Therefore, inhalation of volatiles is based on an assumed estimate that five hours are spent at a moderate activity level (i.e., bending, digging, weeding and mulching), and the rest of the workday is divided between light and heavy (digging, hoeing) activities. The following exhibits the calculation performed:

Activity Level	Hours/Day	Inhalation Rate, m^3/hr	Time-weighted Inhalation Rate, m^3/day
Light	1.5	0.6	0.9
Moderate	5	2.1	10.5
Heavy	1.5	3.9	5.9
Total	8	Rate/workday:	17.3
		Rate/hr:	2.2

Therefore, an inhalation rate of 2.2 m^3/hr, is used for agricultural workers.

It is assumed dirt-bike riding is a moderately heavy activity, and a value of 2.5 m^3/hour is used as the inhalation rate for the dirt-bike rider (USEPA 1989b).

Ingestion of Surface Water. An estimated water ingestion rate while swimming is 0.05 liter per hour (USEPA 1989a). It is assumed that wading activities involve considerably less surface water ingestion. A value of 0.025 liter per event (or one-half a swimming ingestion rate) is assumed in the absence of any other data.

Permeability Constant. An additional parameter needed to calculate dermal intake from water is the permeability constant (PC), in cm/hr (USEPA 1989a). This is a chemical-specific value based on toxicological parameters. The specific PC values used are discussed in detail in Section 4.3.

Summary

Tables 3-5 through 3-11 present calculations of individual HIF values. The resulting HIF values are summarized in Table 3-12.

3.3.3 Calculation of Average Daily Intakes

Average daily intakes (subchronic, chronic and lifetime) were calculated using the exposure point concentrations derived as described in Section 3.3.1 and HIF terms derived as described in Section 3.3.2. These calculations are summarized in Appendix 5.

TABLE 3-5 HIF CALCULATIONS FOR INCIDENTAL INGESTION OF SOIL

Basic HIF Equation:[a] $(kg/kg\text{-}day) = \frac{IR_1 \times CF \times FI \times EF \times ED_1}{BW_1 \times AT_1}$

Time-Weighted HIF Equation[b] $(kg/kg\text{-}day) = \frac{(IR_1 \times EF \times ED_1/BW_1) + (IR_2 \times EF \times ED_2/BW_2) \times FI \times CF}{AT}$

4.0 TOXICITY ASSESSMENT

The purpose of this section of the risk assessment is to summarize the available evidence regarding the nature and extent of adverse health effects that the chemicals of potential concern could produce in an exposed individual. The toxic effects of a chemical depend not only upon its inherent toxicity and the level of exposure (dose), but also upon the route of exposure (oral, inhalation, dermal) and the duration of exposure (subchronic, chronic or lifetime). Thus, a complete description of the toxic effects of a chemical includes a list of the effects the chemical may cause and an analysis of how these effects depend on dose, route and exposure duration. When data permit, the USEPA derives numeric values useful in quantifying the noncarcinogenic and carcinogenic effects of chemicals. These values are described in the following sections.

4.1 Noncarcinogenic Effects

For noncarcinogenic health effects, the toxicity values are termed reference doses (RfDs). These values are both route specific (oral and inhalation) and duration specific (chronic and subchronic). The RfD is an estimate of the average daily intake that may occur without appreciable risk of any adverse effect. The RfD is usually calculated from experimental data, which identify a No-Observed-Adverse-Effect Level (NOAEL) or a Lowest-Observed-Adverse-Effect Level (LOAEL) in animals or humans. Because the experimental data vary in quality and quantity among chemicals, USEPA also provides an indication of the level of confidence associated with the RfD value. In general, the lower the confidence, the more conservative USEPA is in deriving the RfD. Table 4-1 summarizes the noncancer effects of the chemicals of potential concern identified at this site. The table also contains available RfD values and the confidence categories for all verified RfDs.

4.2 Carcinogenic Effects

For cancer the numeric descriptors of carcinogenic potency are termed Slope Factors (SFs). These are route-specific estimates of the slope of the dose-response curve at low doses. It is assumed the curve is linear in this region and passes through the origin. The units of the SF are $(mg/kg\text{-}day)^{-1}$. To ensure an adequate margin of safety, the SF is taken to be the upper 95th percent confidence limit of the slope. Thus, the actual slope factors could be lower but are not likely to be higher. Table 4-2 summarizes the slope factors available for chemicals of potential concern identified at the Himco Dump site.

TABLE 4-1 SUMMARY OF NONCARCINOGENIC EFFECTS AND CRITICAL TOXICITY VALUES FOR CHEMICALS OF POTENTIAL CONCERN AT THE HIMCO DUMP SITE[a]

TABLE 4-2 SUMMARY OF CARCINOGENIC EFFECTS AND SLOPE FACTORS FOR CHEMICALS OF POTENTIAL CONCERN AT THE HIMCO DUMP SITE[a]

Chemical	Target - Route	Weight of Evidence	Slope Factor, (mg/kg-day)$^{-1}$ Oral	Inhalation
Aldrin	Liver-oral	B2	1.7E+01	1.7E+01
alpha-Chlordane	Liver-oral	B2	1.3E+00	1.3E+00
Polychlorinated Biphenyl (Aroclor-1248)[b]	Liver-oral; inadequate but suggestive evidence of liver cancer by inhalation and dermal routes	B2	7.7E+00[b]	--
Arsenic	Lung-inhalation; skin cancer-ingestion; limited evidence of other internal cancers by both routes	A	1.8E+00	1.5E+01
Benzene	Nonlymphocytic leukemia-inhalation and oral	A	2.9E-02	2.9E-02
beta-BHC	Liver-oral	C	1.8E+00	1.8E+00
Benzo(a)pyrene	Stomach-ingestion; respiratory tract-inhalation; skin-dermal[c]	B2	1.2E+01	6.1E+00
Beryllium	Lung cancer-inhalation. Osteosarcomas-injection (intravenous or intramedullary)	B2	4.3E+00	8.4E+00

-continued-

(a) Information from IRIS Database (USEPA 1992b) or HEAST Tables (USEPA 1991c) unless otherwise noted. Only chemicals with slope factors calculated by EPA are included here.
(b) Evaluated by using the slope factor developed for Aroclor-1260.
(c) Other carcinogenic PAHs evaluated using the benzo(a)pyrene slope factor are:

Benzo(a)anthracene	Chrysene
Benzo(b)fluoranthene	Dibenz(a,h)anthracene
Benzo(k)fluoranthene	Indeno(1,2,3-cd)pyrene

Table 4-2 - continued

Chemical	Target - Route	Weight of Evidence	Slope Factor, (mg/kg-day)$^{-1}$ Oral	Inhalation
bis(2-ethylhexyl)phthalate	Liver-ingestion	B2	1.4E-02	--
Bromodichloromethane	Kidney, large intestine and liver tumors by the oral route	B2	1.3E-01	--
Cadmium	Lung, prostate-inhalation; insufficient evidence of carcinogenicity by oral	B1 (inhalation)	--	6.3E+00
Chloroform	Kidney and liver-inhalation and ingestion	B2	6.1E-03	8.1E-02
Chromium (VI)	Lung-inhalation	A (inhalation)	--	4.2E+01
4,4'-DDE	Liver-oral	B2	3.4E-01	--
4,4'-DDT	Liver tumors-oral	B2	3.4E-01	3.4E-01
1,4-Dichlorobenzene	Liver tumors-oral	C	2.4E-02	--
1,1-Dichloroethene	Adrenal-oral, kidney-inhalation	C	6.0E-01	1.8E-01
Dieldrin	Liver, lung-oral	B2	1.6E+01	1.6E+01
gamma-Chlordane	Liver-oral	B2	1.3E+00	1.3E+00
Heptachlor	Liver-oral	B2	4.5E+00	4.6E+00
Lead	Renal tumors-oral (ATSDR 1988a)	B2	--	--
Methylene chloride	Liver-oral and inhalation	B2	7.5E-03	1.6E-03
Styrene	Leukemia-inhalation; lung and bronchi-oral	B2	3.0E-02	2.0E-03

Table 4-2 - continued

Chemical	Target - Route	Weight of Evidence	Slope Factor, $(mg/kg\text{-}day)^{-1}$ Oral	Slope Factor, $(mg/kg\text{-}day)^{-1}$ Inhalation
Tetrachloroethene	Liver-inhalation and ingestion; leukemia-inhalation	B2	5.1E-02	1.8E-03
Trichloroethene	Liver-ingestion; lung cancer-inhalation	B2	1.1E-02	6.0E-03
Vinyl chloride	Lung-oral; liver-inhalation	A	1.9E+00	2.9E-01

The USEPA also assigns weight-of-evidence classification to reflect the overall confidence that the chemical is likely to cause cancer in humans. These categories and their meanings are summarized as follows:

Group A	Known human carcinogen
Group B1 or B2	Probable human carcinogen (B1 indicates the availability of limited human data; B2 indicates sufficient evidence in animals but inadequate or no evidence in humans)
Group C	Possible human carcinogen
Group D	Not classifiable as to human carcinogenicity
Group E	Evidence of noncarcinogenicity for humans

4.3 Dermal Toxicity Values

Since dermal exposures to surface water and groundwater are also of concern at the site, dermal toxicity values are also required. It is important to note that dermal toxicity values must be based on the absorbed dose (rather than the exposed or administered dose), since dermal intakes are calculated as absorbed doses. Since the USEPA has not yet established any dermal toxicity values, approximate values were derived by extrapolation from oral toxicity values. This was done by multiplying the oral subchronic or chronic RfD values by the oral absorption fraction (AF_o), and dividing the oral slope factor by the oral absorption fraction. Absorption fractions are chemical-specific values obtained from toxicokinetic studies including, if available, the studies used in determining oral toxicity values. This approach is based on the assumption that equal absorbed doses are equitoxic. For all the organic chemicals of potential concern at the site, the AF_o was assumed to be 1.0 (i.e., 100% oral absorption). Most organic compounds are fairly well absorbed from the gastrointestinal tract. This is, however, not the most conservative approach since a lower AF_o would result in a lower RfD or higher slope factor. Risk may, therefore, be underestimated. No extrapolation from oral to dermal was performed for any PAHs, since these chemicals act at the point of contact (skin, stomach, lungs) and inter-route extrapolation is inappropriate. Oral absorption of metals is quite variable, with values ranging from 0.1% to 60%, while absorption of arsenic is estimated to be 100% (Owen 1990, Seiler and Bigel 1988, Friberg et al. 1986). Therefore, individual AF_o values for inorganic chemicals of potential concern were used to calculate dermal toxicity values. Dermal toxicity values are summarized in Table 4-3.

In evaluating dermal exposures in water another toxicological parameter, the Permeability Constant (PC), is required. Permeability constants reflect the movement of a chemical across the skin into the bloodstream. Permeability constants have been determined experimentally for a limited number of chemicals. Those available are summarized on Table 4-3. Permeability constants can also be estimated based on the molecular weight and log K_{ow} of each chemical. Calculated PC values are also summarized on Table 4-3.

4.4 Chemicals with No Toxicity Values

Inspection of Tables 4-1 and 4-2 indicates that there are a number of chemicals for which there are no toxicity values. In the case of lead, considerable controversy exists concerning the appropriate toxicity value. In this risk assessment, lead was evaluated using the Uptake/Biokinetic (UBK) model (see Section 5.3). The potential risk of exposure to the other chemicals is not quantified and is addressed as a source of uncertainty in Section 6.0.

5.0 RISK CHARACTERIZATION

Risk characterization integrates the results of the exposure and toxicity assessments into a quantitative description of cancer and noncancer risk estimates. The method for risk characterization utilized in this baseline risk assessment is consistent with guidance provided in USEPA (1989a).

5.1 Evaluation of Carcinogenic Risks

The risk of cancer from exposure to a chemical is described in terms of the probability that an individual exposed for his or her entire lifetime will develop cancer by age 70. For each chemical of concern, this value is calculated from the daily intake, averaged over a lifetime (DI_L), and the SF for the chemical, as follows:

$$\text{Cancer Risk} = 1 - \exp(-DI_L \times SF) \quad (3)$$

In most cases (except when the product of DI_L x SF is larger than about 0.01), excess cancer risk may be estimated more simply as:

$$\text{Cancer Risk} = DI_L \times SF \quad (4)$$

Excess cancer risks are summed across all chemicals of potential concern and all exposure pathways that contribute to exposure of an individual in a given population. Typically, the USEPA requires remedial action at a site when total excess cancer risk levels to any current or future population exceed 1E-04 (USEPA 1991d).

Using the average lifetime daily intake values calculated as described in Section 3.3.2 and the slope factors described in Section 4.0 (Table 4-2), estimated cancer risks were calculated for populations assumed to be exposed at the Himco Dump site. Risk estimates for each population are summarized on Tables 5-1 through 5-3. The chemical- and medium-specific calculations are presented in Appendix 6. Due to the inherent uncertainty in cancer risk calculations, all risk values are reported to only one significant figure.

Estimated cancer risks to current populations are summarized in Table 5-1. There is no reason for concern for carcinogenic effects via these pathways. The risks to the nearest downwind resident from particulate and volatiles emissions from the site are estimated at 2E-07 for adults and 3E-06 for children. Risks to the dirt-bike rider are estimated at 4E-06. The estimated risks to the waders exposed at the quarry pit and ponds are 4E-08 and 2E-08, respectively.

Carcinogenic risks to hypothetical future residential populations are summarized in Table 5-2. Excess carcinogenic risks to hypothetical future

TABLE 5-1 SUMMARY OF ESTIMATED CARCINOGENIC RISK - CURRENT POPULATIONS

Exposed Population	Exposure Point	Exposure Medium	Exposure Route	Total Excess Cancer Risk
Dirt-bike rider	Site	Soil	Ingestion	2E-06
		Air	Inhalation - Particulates	2E-06
			Inhalation - VOCs	2E-08

			Total	3E-06

residents living on the landfill and utilizing groundwater below the site are estimated at 7E-01 (children) to 2E-01 (adults). This risk is the result of exposures to groundwater contaminated with arsenic (3E-04), PAHs (2E-03) and vinyl chloride (1E-03). The remaining estimated carcinogenic risk is attributable to beryllium, which was not detected in leachate samples but was evaluated at one-half its detection limit.

If a residence were to be built just south of the landfill, use of groundwater in this area could pose a cancer risk of approximately 5E-03. As described previously, the method for calculating risks included the assumption that chemicals detected in soil or elsewhere in groundwater (including the leachate samples), but not in the wells located south of the landfill, were evaluated at one-half their detection limit (see Section 3.3.1). This assumption, then, conservatively assumes that the chemicals detected in soil or in groundwater beneath the landfill are not truly absent at downgradient locations, but are present at concentrations just below what the analytical laboratory can measure. Thus, the 5E-3 estimated cancer risk assumes the presence of all those chemicals detected in soil, leachate water or other groundwater samples. If these chemicals are truly absent, that is, the conditions below the landfill are such that these chemicals are not mobile and are not moving away from the landfill, then estimated risks would be much lower. Table 5-4 summarizes the 15 chemicals evaluated at one-half their detection limit, which contribute a carcinogenic risk of at least 1E-6 for hypothetical future residents south of the landfill. The table demonstrates that approximately 80% of the estimated risk downgradient of the landfill is attributable to these "nondetected" chemicals. If these chemicals are truly absent, total population cancer risks would be estimated at 1E-3 due primarily to the presence of arsenic and beryllium in groundwater and PAHs in soil.

Table 5-3 summarizes estimated cancer risks if future development of the site were commercial or agricultural instead of residential. If the future site use is commercial, a plant worker's excess cancer risk is estimated to range from 1E-03 to 4E-02 depending on whether a plant were built on or south of the landfill. As for residential populations, contaminated groundwater contributes the major portion of this risk.

If the site were to revert to agricultural uses, the risk to a hypothetical agricultural worker is estimated at 3E-03 due to contaminated groundwater ingested while working. Under a future agricultural land use condition, a downwind resident's risk due to increased mechanical erosion from tilling minimally affects risk estimates for downwind residents. These calculated risks (2E-06 to 3E-06) are within an acceptable risk range (i.e., they are less than 1E-04).

TABLE 5-4 SUMMARY OF CARCINOGENIC RISKS DUE TO NONDETECTED CHEMICALS

Chemical[a]	Estimated Carcinogenic Risk - South of Landfill[b]
1,1-Dichlorethene	5E-05
Aldrin	5E-06

Styrene	2E-06
Tetrachloroethlene	3E-06
Vinyl chloride	1E-04
Total, Nondetected Chemicals:	4E-03
Total, All Chemicals :	5E-03

(a) Chemicals detected in soil or groundwater (at other sampling locations) and assumed to be present (i.e., evaluated at one-half their reported detection limit).
(b) Analysis for adult resident only, utilizing shallow groundwater.

5.2 Evaluation of Noncarcinogenic Effects

The potential for noncarcinogenic effects is evaluated by comparing an estimated intake for a chemical over a specific time period with the RfD for that chemical derived from a similar exposure period. This comparison results in a noncancer hazard quotient as follows:

$$HQ = DI/RfD \quad (5)$$

where:

HQ = Hazard Quotient for subchronic (HQ_s) or chronic (HQ_c) exposure
DI = Daily Intake (mg/kg-day), either from subchronic (DI_s) or chronic (DI_c) exposure
RfD = Reference Dose (mg/kg-day), either for subchronic (RfD_s) or chronic (RfD_c) exposure

Since exposure occurs simultaneously to more than one chemical, HQ values are summed as follows:

$$HI = HQ_1 + HQ_2 + HQ_3 \ldots\ldots HQ_i \quad (6)$$

where:

HI = Screening level hazard index for either subchronic or chronic exposure
HQ_1 = Hazard Quotient for the first chemical
HQ_i = Hazard Quotient for the ith chemical

The HQ values all represent the same exposure period and are summed for all chemicals and all pathways that contribute to the exposure of an individual in a given population. If the screening level HI is equal to or less than one (1E+00), it is believed noncarcinogenic health effects will not occur. If an HI exceeds 1E+00, there is some possibility that noncarcinogenic effects could exist although an HI above 1E+00 does not indicate an effect will occur. In particular, the screening level approach assumes that all noncancer effects are additive. However, in some cases, effects caused by one chemical on a particular tissue (e.g., the liver) will not be influenced by the effects of another chemical on a different tissue (e.g., the kidney). Thus, when the screening level HI exceeds 1E+00, it may be necessary to perform a more detailed analysis in which effects are summed after segregation according to target tissue (USEPA 1989a).

The methods for calculation of average daily intakes (DI_s and DI_c) were summarized in Section 3.3.2, and chemical-specific RfD values were summarized in Table 4-1. Based on these, HQ and HI values for subchronic (HI_s) and chronic (HI_c) exposures were calculated for each exposure scenario evaluated

at this site. Because of the uncertainty inherent in calculation of HQ values, all HQs are reported to only one significant figure. The detailed calculations are presented in Appendix 5 and results are summarized in Tables 5-5 through 5-7.

All estimated noncarcinogenic risks for current populations are well below a level of concern. However, for all assumed future residential and worker populations that include a groundwater pathway (except for the plant worker, south of the landfill) hazard indices exceed 1E+00.

Subchronic hazard indices for child residents range from 10 to 1,000; chronic hazard indices range from 5 to 500 for adult residential populations. Antimony is the primary contributor to this risk. Other chemicals whose hazard quotients exceed 1.0 include arsenic, beryllium, cadmium, chromium, vanadium, alpha-chlordane and nitrate/nitrite.

As was done for carcinogenic risks, the effect of "nondetected" chemicals on the calculation of HI values was analyzed. There are relatively few chemicals with noncarcinogenic health effects which, when evaluated at one-half their detection limit, will give an HQ greater than one. Alpha-chlordane, beryllium and nitrate/nitrite are the only three chemicals of potential concern at Himco where this is an issue. Nitrate/nitrite was not detected in the shallow groundwater, yet when evaluated at one-half its detection limit, would result in an estimated HQ of 10 (half of the HI value of 20 estimated for child resident population). Beryllium was not detected in leachate samples (and was therefore evaluated at one half its detection limit) and the resulting HQ of 100 is 10% of the total HI of 1,000 (child resident). For child residential populations south of the landfill, the assumption that alpha-chlordane is present results in an HQ of 3 for this chemical (the HI is 20).

The only nongroundwater pathway contributing unacceptable noncarcinogenic risk is the air particulate pathway for the hypothetical future agricultural worker. A chronic hazard index of 4E+00 was calculated for this pathway. This risk is due entirely to chromium.

Since each chemical itself contributes an HQ greater than 1E+00, there is no need to segregate chemicals by effect.

5.3 Evaluation of Risks from Lead Exposure

Since there are no EPA-approved RfD values for lead, it is not possible to evaluate the noncancer risks of lead by calculation of a HI. An alternative approach is to estimate the likely effect of lead exposure on the concentration of lead in the blood (PbB). Several mathematical models have been developed for calculating the value of PbB as a function of environmental concentrations of lead (USEPA 1989c). Of these, the Uptake/Biokinetic (UBK) model has the greatest flexibility and has been most thoroughly validated, so it is selected for use here. The basic equation for calculating PbB with the UBK model is:

$$PbB = (\Sigma\ C_i \times I_i \times ABS_i) \times BKSF \qquad (7)$$

TABLE 5-5 SUMMARY OF NONCARCINOGENIC RISK - CURRENT POPULATIONS

			Total	6E-02

(a) Hazard index is subchronic for child populations and chronic for all others.

where:

C_i = Concentration of lead in medium i (µg/unit medium)
I_i = Human intake of medium i (units medium/day)
ABS_i = Absorption fraction of lead from medium i (unitless)
BKSF = Biokinetic slope factor relating blood lead to absorbed dose. The units of BKSF are µg/dL per µg/day

In general, the values of I, ABS and BKSF are all age dependent, and the value of PbB at any given age is a complex function of both current and past lead exposure levels. It is commonly agreed that young children are more susceptible to the effects of lead than older children or adults, since young children tend to have higher exposure levels (especially to soil), young children have higher lead absorption rates and the nervous system of infants and young children is more sensitive to the neurological effects of lead.

The USEPA has developed a computer program ("LEAD5") for calculating lead exposure and resulting PbB values for children age zero to six years. This computer program was used to evaluate the effects of lead in environmental media on children at this site. The calculations include lead exposure from all sources (including food and area-wide emissions to air), and not just those specifically derived from the site (soil, water and/or air). Most input parameters (e.g., body weight, water intake, soil intake, breathing rate and lead intake from the diet) were taken to be the national average values suggested as defaults by the USEPA. The concentrations of lead in soil and water were site-specific average (not AM_{95}) values calculated as detailed in Appendix 5 for the specific exposure scenarios. The concentrations of air for those populations exposed to site emissions were site-specific average values plus the concentration of the default exposure, assuming the site emissions are episodic increases of lead concentrations in air due to wind and vehicular erosion.

Although there is no universally agreed upon value of PbB that may be identified as "safe" for the effects of lead on children, the USEPA has identified 10 µg/dL as the level of concern for health effects in children that warrants avoidance (USEPA 1988e). The USEPA also recommends that, for a given exposed population of children, no more than 5% should exceed the 10 µg/dL level. Table 5-8 summarizes the predicted geometric mean blood lead level and the percentile of the population predicted to exceed 10 µg/dL for each exposed population. As shown in Table 5-8, geometric blood lead values are predicted to range from 3 to 100 µg/dL for the various populations. It appears that the lead in groundwater beneath the landfill area is a cause for concern at this site.

5.4 Evaluation of Risks by Source

In this risk characterization, risk estimates have been calculated without regard to the source of the contamination. That is, all chemicals detected during the RI sampling were assumed to be site-related. Thus the risk estimates represent total risk to the assumed exposed populations. There is some question as to whether some of the calculated risks could be attributable

TABLE 5-8 SUMMARY OF RISKS TO CHILDREN FROM EXPOSURE[(a)] TO LEAD

Population	Location-Specific Data: Water Lead Conc., µg/L	Soil Lead Conc., µg/g	Air Lead Conc., µg/m^3	Mean PbB, µg/dL	% Population above 10 µg/dL
Current Populations:					
Downwind Child Resident	--	--	0.2	3.24	0.06
Future Populations:					
Child Resident South of Landfill					
- shallow well	50	73	--	5.12	2.7
- deep well	2.1	73	--	2.04	0
Child Resident on Landfill	5,100	2.5	0.2	106.01	100

(a) The following default values were used when location-specific data were not available: Air = 0.2 mg/m^3, Water = 4 µg/L, Soil = 200 µg/g, Food = 6.38 µg/day.

to background, either natural or relative to other sources. In an effort to quantify background risk, risk estimates were developed for exposures to samples from background groundwater and soil locations (as described in Section 2.0) for an assumed hypothetical future adult residential scenario. These results are summarized on Table 5-9. Arsenic, beryllium, bromodichloromethane, chloroform and bis(2-ethylhexyl)phthalate were detected in background groundwater at concentrations that contribute excess cancer risk in the range of 6E-4. Arsenic and nitrate/nitrite dominate the noncarcinogenic risks. The source of the arsenic and beryllium appears to be natural; the source of the nitrate/nitrite is unknown but may be related to the previous agricultural use of the site. The source of the other organic chemicals is presently unknown.

5.5 Risk Summary

The greatest cause for health concern at the Himco site is the hypothetical future use of groundwater below the landfill. Risks from ingestion, dermal contact and inhalation of volatiles from this groundwater present carcinogenic risks in the range of 1E-01 (although a significant portion of this risk is due to undetected beryllium, assumed to be present). Hazard index values for these pathways are approximately 500 to 1,000. Further downgradient of the landfill (south), the estimated excess cancer risks to a future resident are approximately 5E-3. Virtually all this risk, however, is attributable either to chemicals not detected, but conservatively evaluated as if they were present, or to chemicals attributable to upgradient or background sources. It therefore appears that although groundwater beneath the landfill is contaminated, this contamination has not moved (or at least has not been detected) at downgradient exposure points south of the landfill or has been diluted to undetectable levels.

In addition to groundwater, there is an estimated excess cancer risk of 4 to 6E-04 to a future resident living south of the landfill where PAHs were detected in the soil. If the site were to revert to an agricultural use, there could be cause for concern via tilling due to chromium present in the landfill soil at a level (4.7 mg/kg) below that detected in background (7.1 mg/kg).

Other future land uses which do not involve groundwater and current uses of the site do not present excess cancer risks greater than 1E-04 or hazard indices greater than 1E+00.

TABLE 5-9 COMPARISON OF TOTAL SITE AND BACKGROUND RISKS

Exposure Routes	Estimated Carcinogenic Risk				Estimated Noncarcinogenic Risk			
		Total Site				Total Site		
	Background[a]	Shallow Well[b]	Deep Well[b]	Landfill Area	Background[a]	Shallow Well[c]	Deep Well[c]	Landfill Area[d]
Groundwater

(c) From Table 5-2.
(d) From Table 5-6.

6.0 ASSESSMENT OF UNCERTAINTIES

There are a number of factors that contribute uncertainty to the estimates of exposure and risk. The most important of these are discussed in this Section.

Selection of Contaminants of Potential Concern

The selection of contaminants of potential concern was designed to include all chemicals identified at the site that are most likely to be of human health concern. Two procedures were used to eliminate chemicals (nondetection and nutritional essentiality). The chemicals not selected because of nutritional essentiality have low toxicity and their elimination is unlikely to result in an underestimation of risk. Elimination of the remaining chemicals because they were not detected in any environmental sample is, however, a source of some uncertainty, because of the possibility that some of these chemicals may actually have been present, but at levels below detection limits. To evaluate the magnitude of the uncertainty associated with excluding these chemicals, a calculation was performed to determine the risk these chemicals might pose if they were indeed present at the detection limit (Table 6-1). This table evaluates the chemicals never detected at Himco for which excess lifetime cancer risks would equal or exceed 1E-06 either in groundwater or soil assuming the dominant pathways quantified in this risk assessment. For hexachlorobenzene in groundwater there may be some concern since this risk estimate exceeds 1E-04.

It is important to remember that there is no reason to believe these chemicals are actually present at Himco at least at levels approaching detection limits. Nonetheless, this is a source of uncertainty that could result in an underestimate of risk.

Another source of uncertainty is the potential risk posed by exposure to tentatively identified compounds in groundwater, soil and sediment. The identity, concentration and toxicity of these chemicals are uncertain and therefore were not evaluated.

Exposure Pathways Not Evaluated

Not all potentially complete exposure pathways were quantified at this site. Each of these pathways does contribute some risk and, therefore, may lead to an underestimate of risk. Since total risk to a human is a sum of all complete pathways known to exist, the lack of quantification of these pathways may underestimate risk. It is believed that those pathways not quantified generally represent small sources of exposure.

Ingestion of home-grown crops (vegetables or fruits) contaminated by bioaccumulation of chemicals in soil or deposition of particulates onto plant leaves was not evaluated. The uptake of contaminants by plants is subject to considerable uncertainty (USEPA 1991c). Additional uncertainty results from determining exposure point concentrations because it is likely contaminated soils would be tilled, fertilized and mixed with soil enhancers (such as peat, manure, etc.). The underestimate of risk from not evaluating this pathway

TABLE 6-1 ESTIMATED CANCER RISK AT THE DETECTION LIMIT FOR CHEMICALS NEVER DETECTED

Chemical	Water		Soil

(a) U-Value is reported concentration associated with the highest U-value.
(b) Risk calculated by assuming ingestion of water by an adult plus inhalation of VOCs (USEPA 1989a).
(c) Risk calculated by assuming ingestion of surface soil only.

could potentially be substantial, since a reasonable maximum value for home-grown vegetable consumption is 80 g/day (USEPA 1989a), which is 800 times greater than the reasonable maximum value for ingestion of soil by adults. Therefore, for any contaminant that accumulates with a ratio greater than 1:800 in vegetables compared to soil, the home-grown produce pathway could dominate risk.

Environmental Fate and Transport

The evaluation of human health risks assumed that environmental media concentrations determined from sampling will remain at the same levels over a the assumed periods of exposure. This assumption is likely to result in an overestimate of risk, since concentrations, especially of organic contaminants, are expected to decline over the long-term as natural fate and transport processes degrade, dilute or remove site contaminants. The rate of the degradation, removal and/or dilution of chemicals in soil, groundwater, surface water and sediment is not known therefore the magnitude of the overestimate is difficult to estimate.

On the other hand, if contaminants only detected in leachate during the RI begin to move to downgradient wells for some reason (for instance, an increase in pumping in the area because of commercial or residential development), then risks to those populations south of the landfill could be underestimated. It is unlikely, however, that those risks would be higher than the risks calculated from exposure to groundwater directly below the landfill (as represented by the leachate samples).

Estimation of Exposure Point Concentrations

The exposure point concentrations used for assessing risks are the upper 95th confidence limit of the arithmetic mean values of measured concentrations or the maximum detected value if the upper 95th confidence limit exceeded the maximum detected value. Nondetected values were treated as concentrations equal to either zero or half the detection limit. This procedure could underestimate or overestimate risk depending on the actual concentrations (if present) of the chemical reported below the detection limits. This uncertainty is most likely when estimating concentrations for those chemicals detected infrequently.

At the Himco Dump site, the fate and transport of specific chemicals is not fully characterized. The evidence indicates that contamination is migrating from soil to groundwater. Therefore, any chemical of potential concern in soil was also evaluated in groundwater. In addition, it is evident that the highest level of contaminantion occurs in leachate water. Chemicals detected in leachate samples, but not detected in groundwater samples down gradient of the landfill were evaluated at one-half their detection limit. This assumption could over or underestimate risk depending on whether those chemicals are not moving toward those wells or whether they are indeed present downgradient at levels below laboratory detection limits. All other detected chemicals of potential concern were evaluated dependent on their detection in that medium. This may result in an underestimate of risk.

An additional uncertainty is introduced by the use of surface soil concentrations for calculating daily intake resulting from incidental ingestion of soil/dust by hypothetical future adult and child residents. The assumption --that all ingested soil is as contaminated as surface soil near a future residence-- increases the conservatism of the risk assessment by an amount that is dependent upon the actual fraction of ingested soil that is not contaminated by site-related chemicals.

Soil Sampling and Quantification of Exposure

Surficial soil from zero to six to twelve inches is the depth of soil considered most likely to be available for exposure. However, at this site the surficial soil samples utilized in this risk assessment were taken up to 24 inches in depth and samples taken in the landfilled area were taken three to nine inches below the cover material. The quantification of soil exposures assuming all surficial soil is available for contact or intake may overestimate or underestimate risk.

It should also be noted that the assumption that exposure to soils would be limited to surficial depths may underestimate risk because of the nature of contamination at this site, i.e., several volatile and semivolatile chemicals increase in concentration with depth. Thus, if any future activities brought subsurface soil to the surface, risks could be higher.

Exposure Levels

The amount of exposure which an individual receives is highly dependent on the details related to their human activity patterns. As discussed in Section 3.3.2, there is considerable uncertainty regarding the values assumed in calculating human intake factors. For instance, estimates of soil ingestion rates for all populations is subject to on-going debate.

When faced with significant uncertainties in the appropriate values to use in the derivation of HIF terms, an effort was made to employ conservative (but not entirely unrealistic) and standard (USEPA 1991c) values. As a result of this approach, it is likely that some calculated estimates of risk are higher than actual, but it is unlikely that any of the calculated risks are significantly lower.

Bioavailability

When chemicals are present in soil, the amount absorbed into the body when the soil is ingested or inhaled may be less than the amount absorbed when the chemicals are administered in pure form. Thus, the actual dose may be lower for exposed humans than for the experimental animals upon which most toxicity values are based. This may be particularly true for metals. No correction for bioavailability has been made in this assessment which may result in some overestimate of risk.

Concentration of Volatiles from Household Uses of Water

Inhalation of volatiles released from groundwater via household uses was evaluated by assuming that the intake was twice that from ingestion of water. Actual worst-case estimates typically range from one to six times ingestion exposure. The value of two times ingestion exposure may underestimate risk to individuals with high water usage in poorly ventilated homes.

Assumptions and Parameters Used in Modeling the Air Pathway

When models are used to calculate exposure point concentrations, uncertainty is generated as a result of limitations in the models themselves and because of the uncertainty in the assumptions and the input parameters used.

Estimates of PM_{10} concentrations (Appendix 2) in air resulting from wind and vehicular (dirt-bikes and tractors) erosion of particles from site soils are highly uncertain. This is mainly the result of the lack of site-specific data and the need to employ assumed input parameters. Site-specific information on the area of the site that is disturbed (or would be likely to be disturbed in the hypothetical agricultural scenario) and the number and frequency of site disturbances is unknown. The lack of site information increases the inherent uncertainty of the model which is intended to provide no more than rough estimates.

In the case of inhalation exposure to volatiles released from soil, the risks are sufficiently small that uncertainties in the approach to estimate exposure (Appendix 3) would not significantly influence risk conclusions. For inhalation exposures to volatiles released from groundwater during indoor water usage, risks may be significant and any uncertainties in those calculations could influence subsequent risk estimates.

Absence of Toxicity Values

Quantification of risk from exposure to a chemical cannot be accomplished in the absence of reliable, appropriate toxicity values (reference doses, slope factors) for all routes and exposure periods. For the chemicals of potential concern at the Himco Dump site, toxicity values are not available for some chemicals by some routes. The absence of these values is likely to result in an underestimate of both noncancer and cancer health risks at this site, but is not possible to estimate the magnitude of this underestimate.

Cancer Risk Estimates

The predicted cancer risk due to chemical exposure is often based on cancer dose-response data in animals. There is a long-standing controversy in the scientific community as to the best way by which animal data should be extrapolated to humans. In general, the USEPA follows a conservative procedure in the derivation of slope factors, so cancer risk estimates based on these values could be considerably higher than the true risk.

The cancer risks calculated for children are less certain than those calculated for adults. The method utilized in this risk assessment assumes cancer risks are simply proportional to total dose. Actual cancer risk to a child exposed only in childhood could be higher or lower depending on the detailed mechanism of carcinogenicity for each chemical.

Exposure to Multiple Chemicals

The HI approach assumes that risks from multiple chemicals are additive, ignoring both synergistic and antagonistic effects among chemicals. There is no evidence of synergism among the chemicals evaluated at the Himco Dump site, therefore, the assumption of dose additivity is not likely to be a source of major error.

Summary of Uncertainty

In summary, the estimation of exposure and risk are subject to a number of uncertainties that may lead to either an overestimate or underestimate of risk.

Assumptions made in this risk assessment that are likely to overestimate risk include:

- Environmental media concentrations are unchanged over time.
- All ingested soil comes from the contaminated source.
- Soil is ingested at the assumed rates for all exposed populations.
- Human activity patterns and the resultant exposure factors used to calculate a reasonable maximum exposure are as assumed.
- Slope factors are equal to the 95% confidence limit of the best estimate of the slope of the dose-response curve.

Factors in this risk assessment that are likely to underestimate risk:

- Not all exposure pathways for all chemicals were quantified.
- Toxicity values are not available for every chemical, for every exposure duration or for all exposure routes.
- Chemicals not detected in any media, but possibly present, were not quantified.
- Risks from all TICs were not quantitatively evaluated.
- Risks for chemicals not analyzed for, but possibly present, were not evaluated.

Factors in which the direction of the uncertainty cannot be determined or are unknown include:

- Use of zero or one-half detection limit in calculating exposure point concentrations for samples where a specific chemical was not detected.
- Analytical variations in chemical analyses.
- Lack of information on the interactions among the multiple chemicals contributing to noncancer and cancer risks.
- Assumption of all hypothetical future populations and activities.
- All modeling assumptions and input parameters.
- Method for quantifying less than lifetime exposures to carcinogens (e.g., in childhood).

7.0 SUMMARY

This baseline risk assessment is an analysis of the potential adverse health effects resulting from exposures to contaminants at the Himco Dump site. The site is a closed landfill located in the city of Elkhart, Indiana. The landfill wastes consist primarily of pharmaceutical wastes and calcium sulfate.

The basic methodology used in this risk assessment was developed by the USEPA specifically for evaluation of risk at hazardous waste sites. A baseline risk assessment considers conditions in the absence of any remedial actions to control or mitigate releases (including institutional controls), that is, the no-action alternative. Overall, the methodology used in a baseline risk assessment is intentionally conservative, meaning that the true risks from the site are unlikely to be higher than the derived estimates, and are most likely to be lower. The major elements in this risk assessment are summarized below.

7.1 Selection of Chemicals of Potential Concern

Analytical data on chemical concentrations in soil, groundwater, surface water and sediment were evaluated to identify the chemicals that would form the focus of the quantitative risk assessment.

Chemicals were eliminated from the quantitative risk assessment if they were not detected in any environmental sample or if they were beneficial human nutrients and occurred at levels that did not exceed the beneficial level. The chemicals selected as chemicals of potential concern are listed in Table 7-1.

7.2 Exposure Scenarios Evaluated

An analysis of exposure pathways along with probable human activity patterns, current and future land uses and site contamination was completed to determine complete exposure pathways and to select exposure scenarios for quantification.

Current populations most likely to be exposed are:

- Residents northeast of the site
- Recreational dirt-bike riders
- Recreational visitors (waders, fishers)

Hypothetical future use of the site could include agricultural use or commercial/residential development. The hypothetical future populations most likely to be exposed are:

- Site residents
- Plant workers on site
- Agricultural workers on site
- Downwind off-site residents

Polychlorinated biphenyls (Aroclor 1248)

NON-CLP CHEMICALS:

Bromide, dissolved
Chloride
Nitrogen, ammonia
Nitrogen, nitrate & nitrite
Phosphorus
Sulfate

While other exposure pathways may also exist at this site, they were judged to be relatively minor when compared to those pathways which were quantified. The exposure scenarios that were quantified are listed in Table 7-2.

Each pathway was quantified by:

- Estimating an exposure point concentration (generally the 95th upper confidence limit of the arithmetic average of all samples representative of a given exposure point).
- Estimating a human intake factor which combines all the variables involved in exposure to a contaminant (i.e., ingestion or inhalation rate, exposure duration and frequency, body weight, averaging time).
- Comparing the product of the above (the subchronic, chronic and lifetime daily intakes) to an appropriate toxicity value.

7.3 Risk Summary

Cancer Risks

The risk of cancer from an exposure to a chemical is described in terms of the probability that an individual exposed for a lifetime will develop cancer. Typically, the USEPA requires remediation when total excess cancer risks levels exceed 1E-04 for a given population. Higher cancer risk levels may be a cause for concern. Cancer risks estimated for the Himco Dump site are summarized on Tables 7-3 through 7-5. Due to the inherent uncertainty in cancer risk calculations all risk values are reported to only one significant figure.

Estimated risks for current populations range from 2E-08 (wader) to 4E-06 (dirt bike rider). Estimated cancer risks for future populations are highest for a resident living in a home built on the landfill (7E-01, children; 2E-01, adults). Virtually all of this risk is from groundwater pathways. The major contributors are arsenic, beryllium, PAHs and several volatile organic compounds.

Noncancer Risks

The potential for noncarcinogenic effects is evaluated by summing the ratios of chemical-specific intake over a specific time period to the chemical-specific RfDs derived for a similar exposure period. This cumulative ratio is referred to as a HI. Since some individuals are exposed by more than one pathway, HI values are summed for each pathway that contributes to the exposure of an individual in a given population. If the total HI is equal to or less than 1 (1E+00), it is believed noncarcinogenic health effects will not occur. If a HI exceeds 1E+00, there is some possibility that noncarcinogenic effects may exist although a HI above 1E+00 does not indicate an effect will occur. In particular, summing values assumes that all noncancer effects are additive. Since this is not always true, when a population total HI exceeds 1E+00, it may be appropriate to re-examine the noncancer effects for that

TABLE 7-2 SUMMARY OF EXPOSURE PATHWAYS SELECTED FOR QUANTIFICATION

Land Use	Potentially Exposed Population	Exposure Point	Exposure Medium	Exposure Route
Current	Dirt-bike rider	Site	Soil	Ingestion Inhalation
			Air	- Particulates - VOCs

			Total	3E-06

individual and segregate by effect. Values for subchronic (HI_S) exposures were calculated for all child populations and chronic (HI_C) exposures were calculated for all adult populations. Because of the uncertainty inherent in these calculations, all values are reported to only one significant figure. The results are summarized in Tables 7-6 through 7-8.

No HIs for current populations exceed 1E+00. For hypothetical future populations, HIs are greater than 1E+00 for all populations (except the plant worker south of the landfill), which are assumed to utilize groundwater as drinking water. The calculated HI values range from 5E+00 (adult resident south of the landfill) to 1E+03 (child resident on the landfill). The chemicals contributing to this risk include antimony, arsenic, barium, beryllium, cadmium, chromium, mercury, vanadium, cyanide and nitrate/nitrite. For the hypothetical future agricultural worker, tilling operations on the landfill might result in a HI of 4E+00 (due to inhaled chromium).

Risks from Lead Exposure

Since there are no EPA-approved RfD values for lead, it is not possible to evaluate potential noncancer risks of lead by calculation of a HI. An alternative approach is to estimate the likely effect of lead exposure on the concentration of lead in the blood (PbB). Several mathematical models have been developed for calculating the value of PbB as a function of environmental concentrations of lead. Of these, the Uptake/Biokinetic (UBK) model has the greatest flexibility and has been most thoroughly validated.

It is commonly agreed that young children are more susceptible to the effects of lead than older children or adults, since (1) young children tend to have higher exposure levels (especially to soil), (2) young children have higher lead absorption rates, and (3) the nervous system of infants and young children is more sensitive to the neurological effects of lead. The LEAD5 program was used to evaluate the effects of lead in environmental media on children at the Himco Dump site. It should be noted that these calculations include lead exposure from all sources (including food and area-wide emissions to air), and not just those specifically derived from the site (soil, water and/or air). Site-specific lead concentrations were used when available, although most input parameters (e.g., body weight, water intake, soil intake, breathing rate and lead intake from the diet) were taken to be the national average values suggested as defaults by the USEPA. The concentration of lead in air was taken to be the default value except for those downwind populations exposed to episodic site emissions, in which case, calculated concentrations from the site were added to the default value.

Although there is no universally agreed upon value of PbB that may be identified as "safe" for the effects of lead on children, the USEPA had identified 10 µg/dL as the level of concern for health effects in children that warrant avoidance. The geometric blood lead values predicated for this site range from 3 to 100 µg/dL. On this basis, it appears that lead in groundwater is a cause for concern at this site.

(a) Hazard index is subchronic for child populations and chronic for all others.

Summary

The greatest cause for health concern at the Himco site is the hypothetical future use of groundwater below the landfill. Risks from ingestion, dermal contact and inhalation of volatiles from this groundwater present carcinogenic risks in the range of 1E-01 (although a significant portion of this risk is due to undetected beryllium, assumed to be present). Hazard index values for these pathways are approximately 500 to 1,000. Further downgradient of the landfill (south), the estimated excess cancer risks to a future resident are approximately 5E-3. Virtually all this risk, however, is attributable either to chemicals not detected, but conservatively evaluated as if they were present, or to chemicals attributable to upgradient or background sources. It therefore appears that although groundwater beneath the landfill is contaminated, this contamination has not moved (or at least has not been detected) at downgradient exposure points south of the landfill.

In addition to groundwater, there is an estimated excess cancer risk of 4 to 6E-04 to a future resident living south of the landfill where PAHs were detected in the soil. If the site were to revert to an agricultural use, there could be cause for concern via tilling due to chromium present in the landfill soil at a level (4.7 mg/kg) below that detected in background (7.1 mg/kg).

Other future land uses which do not involve groundwater and current uses of the site do not present excess cancer risks greater than 1E-04 or hazard indices greater than 1E+00.

7.4 Uncertainties

There are many aspects of the risk assessment process where precise evaluations are not possible. These include uncertainties related to estimating levels of contaminants in environmental media, using mathematical models, evaluating the amount of contaminants taken in by humans and predicting the likelihood of adverse health effects.

- The evaluation of human health risks assumed that surface soil, groundwater, surface water and sediment would remain as contaminated in the future as they are at present. This assumption probably results in an overestimate of risk, because some decrease in concentration is probable for the contaminants of potential concern through natural fate and transport processes.

- The determination of the appropriate exposure factors to be used in calculating daily intakes can be uncertain. Standardized exposure factors were used where possible. A few exposure factors were used based on site-specific information. Highly uncertain exposure factors were selected for the recreational populations and the hypothetical future agricultural population. Overall, exposure estimates were intended to be conservative and so could contribute to an overestimate of risk.

- The estimation of air concentrations of particulates and volatiles were made with mathematical models utilizing uncertain input variables. It is not known if this under- or overestimates risk.

- Toxicity values were not available for all combinations of chemicals, durations, routes and endpoints. The absence of these values is likely to result in an underestimate of noncancer and cancer health risks at the site.

- Toxicity values that were used were derived using conservative procedures, particularly for cancer risk, and thus may tend to overestimate risk to the average person.

In summary, most assumptions and professional judgments were intentionally conservative, and thus, likely to overestimate potential exposure or risk. Consequently, the risks estimated for this site should be considered approximate and are more likely to be higher than lower than the true risk.

APPENDIX 2

CALCULATION OF DUST CONCENTRATIONS IN AIR AT THE HIMCO DUMP SITE

1.0 INTRODUCTION

One pathway by which humans may be exposed to site contaminants at the Himco Dump site is by inhalation of airborne dust particles contaminated soil. These particles may be resuspended either from the force of the wind on the soil, or from mechanical erosion such as dirt-bike riding or agricultural tilling. This appendix describes how the concentrations of respirable dust particles (PM_{10}) in air were estimated at each exposure point where air emissions were considered to be a potential exposure pathway. The concentrations of individual chemicals of potential concern were then obtained by multiplying the PM_{10} concentrations (kg/m^3) by the concentrations of contaminants of potential concern in soil (mg/kg).

2.0 EMISSION RATE FROM WIND EROSION - CURRENT AND FUTURE LAND USES

The rate of soil erosion due to wind action is a complex function of wind speed, particle size distribution, extent of ground covered with vegetation and "roughness" of the surrounding terrain. It is assumed that the erodible surfaces of the site include the landfill area and the worn foot and bike trail south of the quarry pit pond. Based on the composition of capping material (sand and calcium sulfate) and the discontinuous vegetation, emission rates were calculated based on the unlimited erosion potential equation (Cowherd et al. 1985), as follows:

$$E = 0.036\ (1-V)(u/ut)^3 F(x) \qquad (1)$$

where:

E = PM_{10} emission factor ($g/m^2/hr$)
V = fraction of surface vegetative cover
u = mean annual wind speed (m/s)
ut = threshold value of wind speed at 2.25 m/s
x = 0.886 ut/u
$F(x)$ = function of x plotted in Cowherd et al. (1985), Figure 4-3

Values for each of these parameters were derived or estimated as follows:

V The value for vegetative cover was estimated at 50% based on site characteristics observed on a site visit by Life Systems' personnel.

u The average annual wind speed was calculated as 2.25 m/s (5.03 mph) based on meterology information from the South Bend/St. Joe weather station (GSC 1989).

ut The value of ut is a function of the Threshold Friction Velocity (TFV) and the roughness height (Z_0). Estimation of the TFV requires information on the mode of the particle size distribution in soil. The aggregate size distribution mode was calculated from the

particle size distribution data provided by Donohue & Associates. The data included an analysis for five surface soil samples (GE-01, GE-05 and HS03-05) on the capped landfill and dirt bike trail (refer to Figure 2-1). The TFV was then estimated, based on the graph in Figure 3-4 of Cowherd et al. (1985) to be 35 cm/sec. The roughness height is a function of the height of natural and manmade objects in the vicinity of the source. Under current land use conditions, the capped landfilled area approximates a wheat field, thus the value of Z_0 was estimated to be 4 cm, based on the graph presented in Figure 3-6 of Cowherd et al. (1985). Employing this roughness height, the ratio of ut to TFV was estimated to be based on the graph in Figure 4-1 of Cowherd et al. (1985). Ut was then calculated by multiplying the TFV by 13, resulting in a value for ut of 4.6 m/s. Under future land use conditions (soybean or corn fields), the values are assumed to be the same.

x This value is calculated as 0.886 (ut/u).

F(x) The F(x) value was estimated from the graph in Figure 4-3 of Cowherd et al. (1985) to be 0.5.

The emission rate was then calculated as follows:

$$E = 0.036\ (1-0.5)(2.25/4.6)^3(0.5)$$
$$= 1.05E\text{-}03\ g/m^2/hr$$

This emission rate was then divided by 3,600 sec/hr to obtain an emission rate of 2.9E-07 $g/m^2/sec$ or 2.9E-10 $kg/m^2/sec$.

3.0 EMISSION RATE FROM DIRT-BIKE RIDING - CURRENT LAND USE

The rate of soil emissions due to vehicular traffic is a function of vehicle speed, weight and the number of wheels, along with the particle size distribution of the soil. Based on Cowherd et al. (1985), the basic equation for estimated emission rates from vehicular traffic on dirt surfaces per vehicle kilometer traveled (VKT) is:

$$E = 0.85 * (S/10) * (V/24)^{0.8} * (W/7)^{0.3} * (T/6)^{1.2} \quad (2)$$

where:

E = PM_{10} emission rate (kg/VKT/hr)
S = Silt content of the soil (%)
V = Vehicle speed (km/hr)
W = Vehicle weight (Mg, where 1 Mg = 1,000 kg)
T = Number of tires (wheels) per vehicle

The values of the parameters above were derived as follow:

S The silt content of the site is based on the grain size analysis data provided by Donohue & Associates. The average silt content was estimated to be 33%.

V The velocity of the dirt-bike riders was assumed to be 30 km/hr (about 20 mph).

W The weight of the dirt-bikes was assumed to be about 0.06 Mg (60 kg). Combined with the weight of the rider (70 kg), the total weight is 0.13 Mg.

T The number of tires (wheels) per dirt bike is two.

Based on these parameters, the value of E (expressed as kg/VKT/hr) was calculated:

$$E = 0.85 \times (33/10) \times (30/24)^{0.8} \times (0.13/7)^{0.3} \times (2/6)^{1.2}$$

$$= 0.27 \text{ kg/VKT/hr}$$

The emission rate for a single dirt-bike rider at this site is calculated by multiplying by VKT (the number of vehicles, assumed to be one, times the speed of each) and dividing by the area of the landfilled area (34,500 m^2 based on site maps) yields the emission rate in units of kg/hr/m^2:

$$E = \frac{0.27 \times 30}{34,500}$$

$$= 2.3E\text{-}04 \text{ kg/hr/m}^2$$

Dividing by 3,600 sec/hr:

$$E = \frac{2.3E\text{-}04}{3,600}$$

$$= 6.5E\text{-}00 \text{ kg/sec/m}^2$$

The emission rate for one dirt-bike rider while on site is 6.5E-08 kg/sec/m^2. This is the emission rate during the dirt-bike riding event and is not an annual average.

On-Site Dirt-Bike Rider

Assuming that two dirt-bike riders ride together during each event, the emission rate would be twice the emission rate for one rider, or 1.3E-07 kg/sec/m^2.

Current Off-site Downwind Resident

Assuming four dirt-bike riders on site and assuming emissions may occur 78 hours per year (see Section 3.0), an average annual emission rate is determined:

$$E = 6.5E\text{-}08 \text{ kg/sec/m}^2 \times 4$$

$$= 2.6E\text{-}07 \text{ kg/sec/m}^2$$

$$E_{(\text{annual average})} = 2.6E\text{-}07 \text{ kg/sec/m}^2 \times \frac{78 \text{ hrs/yr}}{8{,}760 \text{ hr/yr}}$$

$$= 2.3E\text{-}09 \text{ kg/sec/m}^2$$

Therefore, the annual average emission rate from dirt-bike riding on site for the off-site downwind resident is 2.3E-09 kg/sec/m^2.

4.0 CALCULATION OF PM_{10} CONCENTRATIONS IN AIR - CURRENT LAND USE

The concentrations of PM_{10} in air resulting from wind erosion and dirt-bike riding at each area were calculated using the box model (Hanna et al. 1982). The basic equation is:

$$C = (E * X)/(H/2 * u) \qquad (3)$$

where:

C = Concentration of PM_{10} in air (kg/m^3)
E = PM_{10} emission rate ($kg/sec/m^2$)
X = Distance from upwind to downwind edge of the box (m)
H = Mixing height of the box (m)
u = Windspeed (m/sec) across the box

Values of these parameters were derived as follows:

E — The emission rates were calculated as described in Sections 2.0 and 3.0, above.

X — The distance from the upwind to downwind edge of the box was derived by measurement of the sampling map (refer to Figure 2-1) and was determined to be 206 m. The wind was presumed to be blowing from the southwest.

H The mixing height of the box is a function of distance from the source and turbulence of the air which, in turn, is a function of the roughness of the terrain. The value of H at the upwind edge of the site is zero. At the downwind edge, the value of H was calculated from the following equation (Pasquil 1975):

$$X = 6.25\ Z_0[(H/Z_0)\ \ln\ (H/Z_0) - 1.58\ (H/Z_0) + 1.58] \quad (4)$$

where:

X = Upwind to downwind distance (m)
Z_0 = Roughness height (m)

Based on a current roughness height of 4 cm (0.04 m), the value of H was calculated as a function of X to be 8.7 m. The average height over the whole box is then H/2.

u The average wind speed was taken to be 2.25 m/sec, based on wind speed measured at the South Bend/St. Joe weather station.

Current Off-Site Downwind Resident

Employing these input parameters, the concentrations of PM_{10} were calculated for wind erosion and dirt bike riding:

$$C_{(wind)} = (E_{(wind)} \times X)/(H/2 \times u)$$
$$= (2.9E\text{-}10 \times 206)/(8.7/2 \times 2.25)$$
$$= 6.1E\text{-}09\ kg/m^3$$

$$C_{(bike)} = (E_{(bike)} \times X)/(H/2 \times u)$$
$$= (2.3E\text{-}09 \times 206)/(8.7/2 \times 2.25)$$
$$= 4.8E\text{-}08\ kg/m^3$$

Therefore, the PM_{10} concentration for the off-site downwind resident is the total of the PM_{10} concentrations from wind and vehicular erosion:

$$\text{Total } C = C_{(wind)} + C_{(bike)}$$
$$= 6.1E\text{-}09 + 4.8E\text{-}08$$
$$= 5.4E\text{-}08\ kg/m^3$$

Dirt-Bike Rider

During a dirt-bike riding event, the PM_{10} concentration on site may be calculated by the same equation, using the emission rate for two dirt-bike riders:

$$C_{(bike)} = (E_{(bike)} \times X)/(H/2 \times u)$$
$$= (1.3E\text{-}07 \times 206)/(8.7/2 \times 2.25)$$
$$= 2.8E\text{-}06 \text{ kg/m}^3$$

5.0 EMISSION RATE FROM AGRICULTURAL TILLING - FUTURE LAND USE

The emission of soil particles into air during tilling operations depends mainly on the silt content of soil. Since tilling and related operations are usually done only when the soil is reasonably dry, surface moisture content is generally not a key factor. Also, emissions do not depend heavily on the specific tillage implement, if operations are at a normal speed (usually 8 to 10 km/hr). Based on direct measurements, the emissions of soil per unit area during tilling of land is given by USEPA (1988):

$$E = (5.38)(k)(S)^{0.6} \quad (5)$$

where:

E = Emission rate (kg/hectare).
k = Particle size multiplier (percentage of total emissions below a specific size limit).
S = Silt content of surface soil (%).

The value of k for particles less than 10 μm (i.e., PM_{10}) is 0.21 (USEPA 1988d). The silt content is 80% based on grain size analysis data for the two samples located in the former crop area. Based on these parameters, the PM_{10} emission rate is:

$$E = (5.38)(0.21)(80)^{0.6} \quad (6)$$
$$= 15.7 \text{ kg/hectare}$$

Assuming the tractor is moving at 8 km/hr and is pulling an implement about 5 m wide, it will take about 15 minutes to till one hectare (1 hectare = 10,000 m^2 = 2.5 acres). Based on this, the emission rate per unit area may be expressed as:

$$E = 15.7 \text{ kg}/10{,}000 \text{ m}^2/15 \text{ min} \quad (7)$$
$$= 1.0E\text{-}04 \text{ kg/m}^2/\text{min} \div 60 \text{ sec/min}$$
$$= 1.7E\text{-}06 \text{ kg/m}^2/\text{sec}$$

Therefore, the emission rate for an agricultural worker is 1.7E-06 $kg/m^2/sec$. This is the emission rate during tilling and related operations and is not an annual average.

Assuming emissions from agricultural activities occur one hour a day for 10 days a year, an average emission rate is thus determined:

$$E_{(\text{annual average})} = 1.7E\text{-}06\ kg/m^2/sec * \frac{10\ hr/yr}{8{,}760\ hr/yr}$$

$$= 1.9E\text{-}09\ kg/m^2/sec$$

Therefore, the annual average emission rate from agricultural tilling on site for the hypothetical future off-site downwind resident is 1.9E-09 $kg/m^2/sec$.

6.0 CALCULATION OF PM_{10} CONCENTRATIONS IN AIR - FUTURE LAND USE

The concentration of PM_{10} in air resulting from agricultural tilling was calculated using the box model (Hanna et al. 1982). The basic equation is:

$$C = (E \times X)/(H/2 \times u) \qquad (8)$$

where:

C = Concentration of PM_{10} in air (kg/m^3)
E = PM_{10} emission rate ($kg/m^2/sec$)
X = Distance from upwind to downwind edge of the box (m)
H = Mixing height of the box (m)
u = Windspeed across the box (m/sec)

Values of these parameters were derived as follows:

E = The emission rate is 1.7E-06 $kg/m^2/sec$, calculated as described above.
X = The distance from the upwind to downwind edge of the box is assumed to be 206 m (refer to Section 4.0 of this appendix).
H = The value of H is 8.7 m (calculated previously in Section 4.0).
u = The average windspeed is 2.25 m/sec.

Worker

Employing these input parameters, the concentration of PM_{10} in air for an agricultural worker is calculated as follows:

$$C = (1.7E\text{-}06 * 206)/(8.7/2 * 2.25) \qquad (9)$$

$$= 3.6E\text{-}05\ kg/m^3$$

Utilizing the same equation, the concentrations of PM_{10} were calculated for wind erosion (assumed to be the same as the current emission rate) and agricultural tilling:

$$C_{(wind)} = (E_{(wind)} * X)/(H/2 * u)$$
$$= (2.9E-10 * 206)/(8.7/2 * 2.25)$$
$$= 6.1E-09 \text{ kg/m}^3$$

$$C_{tilling}) = (E_{(tilling)} * X)/(H/2 * u)$$
$$= (1.9E-09 * 206)/(8.7/2 * 2.25)$$
$$= 4.0E-08 \text{ kg/m}^3$$

Adding the PM_{10} concentrations from wind erosion and agricultural tilling results in a PM_{10} concentration for the hypothetical future off-site downwind resident.

$$\text{Total C} = C_{(wind)} + C_{(tilling)}$$
$$= 6.1E-09 + 4.0E-08$$
$$= 4.6E-08 \text{ kg/m}^3$$

Table A1-1 summarizes the calculated PM_{10} concentrations (kg/m^3) for each population of concern at the Himco Dump site.

		Wind erosion	6.1E-09
		Total	4.6E-08

APPENDIX 3

DETAILED DESCRIPTION OF MODELS USED TO CALCULATE AIR CONCENTRATIONS OF VOCs RELEASED FROM SOIL

1.0 INTRODUCTION

The concentration of volatile organic chemicals (VOCs) in air that result from releases from contaminated soil is a complex function of soil, chemical and meteorological parameters. Estimation of the concentration values is approached in two steps: first, the emission rate of each volatile from soil is calculated, and then the resultant concentration in air is calculated. Methods used to achieve these steps are detailed below.

2.0 EMISSION MODEL

Hwang (1986) developed a mathematical model for estimating the average emission rate of a chemical from soil that considers the physical-chemical properties of the chemical (its volatility and its tendency to sorb to soil and dissolve in water), and the characteristics of the soil (the amount of organic matter in the soil and the amount of pore space between soil particles). The model assumes that the concentration of a chemical at the surface will tend to decrease over time due to volatilization, so the emission rate also decreases as a function of time.

The basic equation proposed by Hwang (1986) is:

$$Q = C_s \cdot \frac{2 \cdot E \cdot De \cdot H'}{(\pi \cdot \alpha \cdot t)^{1/2} \cdot K_d} \qquad (1)$$

A discussion of the meaning and value of each of the terms in Equation 1 is provided below.

Q — Q is the average emission rate ($g/cm^2 \cdot sec$) of a chemical emitted from soil over time period t.

C_s — C_s is the average concentration of chemical in soil (g/g). The values of C were calculated using the 95th upper confidence limit of the arithmetic mean of the surficial soil samples used in exposure point concentrations.

E — E is the soil porosity (dimensionless). It corresponds to the fraction of total soil volume that is not occupied by solid matter. The value of E is calculated from the following equation:

$$E = 1-(\overline{P}_s/P_s) \qquad (2)$$

where:

$\overline{P}_s$ = Average moist bulk soil density (g/cm^3)
P_s = True soil density (the density of the solid matter)(g/cm^3)

The value of $\bar{P}_s$ at this site is unknown, but a value of 1.88 g/cm^3 was assumed based on information from the Main Street Well Field site located about one mile to the south-southeast. The value of P_s is not known, but a value of 2.65 g/cm^3 is typical of most soils (Shen 1981). Based on these values, the value of E is

$$E = 1 - (1.88/2.65) \quad (3)$$

$$= 0.29$$

D_e D_e is the effective diffusivity (cm^2/sec) of each chemical. This characterizes the rate of chemical diffusion up through the pore spaces of the soil. It is calculated from the chemical-specific molecular diffusivity constant D (cm^2/sec) and the soil porosity (E), as follows:

$$D_e = D \cdot E^{1/3} \quad (4)$$

Values of D are available for a few chemicals, but most values must be estimated by extrapolation from a reference chemical for which the diffusion coefficient is known (Lyman et al. 1982). The equation for estimating D is:

$$D = D' \left(\frac{MW'}{MW}\right)^{1/2} \quad (5)$$

where:

D = The diffusion coefficient of the chemical of concern
D' = The diffusion coefficient of the reference chemical
MW = The molecular weight of the chemical of concern
MW' = The molecular weight of the reference chemical

Lyman et al. (1982) suggest that an appropriate method of estimating D for a chemical of concern is to calculate D values based on two compounds whose diffusion coefficients are known (carbon disulfide and diethyl ether) and average the two D values.

Table A3-1 illustrates the values of D calculated for each of the volatile chemicals of potential concern at this site.

H' H' (the nondimensional Henry's law constant) is a chemical-specific term that is calculated from Henry's law constant as follows:

$$H' = H/RT \quad (6)$$

where:

H = Henry's law constant (atm-m^3/mol)
R = Gas constant (8.2E-05 atm-m^3/mol-K)
T = Temperature (K)

TABLE A3-1 CHEMICAL SPECIFIC PARAMETERS FOR THE HWANG MODEL

Chemical Name	Molecular Weight[a]	D1[b]	D2[c]	D (avg)
1,1-Dichloroethene	97	9.03E-02	7.77E-02	8.40E-02
2-Butanone	72	1.05E-01	9.02E-02	9.75E-02
Acetone	58	1.17E-01	1.01E-01	1.09E-01
Carbon disulfide	76			1.02E-01[d]
Ethylbenzene	106	8.64E-02	7.44E-02	8.04E-02
Methylene chloride	85	9.64E-02	8.30E-02	8.97E-02
Styrene	104	8.71E-02	7.5E-02	8.11E-02
Tetrachloroethylene	166	6.91E-02	5.95E-02	6.43E-02
Toluene	92	9.27E-02	7.98E-02	8.63E-02
Trichloroethylene	131	7.77E-02	6.69E-02	7.23E-02
Xylenes	106	8.64E-02	7.44E-02	8.04E-02

(a) Values from Howard (1989).
(b) Calculated by extrapolation from carbon disulfide (Lyman et al. 1982).
(c) Calculated by extrapolation from diethyl ether (Lyman et al. 1982).
(d) Known diffusion coefficient.

At 20 C (293 K), the value of RT is 0.024 atm-m^3/mol, and H' is given by:

$$H' = H/0.024 \quad (7)$$

α α is a term that combines several soil- and chemical-specific parameters, as follows:

$$\alpha = \frac{D_e \cdot E}{E+P_s(1-E)(K_d/H')} \quad (8)$$

The values of D_e, E, P_s, and H' have been discussed above. The value of K_d is discussed below.

K_d K_d is the soil-water partition coefficient (cm^3/g). It is a soil- and chemical-specific term, calculated as follows:

$$K_d = K_{oc} \cdot F_{oc} \quad (9)$$

where:

K_{oc} = Organic carbon binding constant (cm^3/g). Published values for the K_{oc} for each chemical of potential concern were used.

F_{oc} = Soil organic carbon fraction (unitless). The value of F_{oc} at this site is estimated to be about 0.1% (0.001), based on information from the Main Street Well Field Site.

t t is the time (seconds) over which the emission rate is averaged. The value of t was chosen to be 6 years (1.9E+08 seconds) for subchronic exposure), 25 years (7.9E+08 seconds) for occupational chronic exposures and 30 years (9.5E+08 seconds) for residential chronic exposures. Since the emission rate decreases as a function of time, it is assumed that all exposures begin at the present. This approach yields the highest possible exposure rates. For example, any adult exposed for 30 years beginning any time in the future would have a lower exposure than for an adult exposed currently.

Based on these input parameters, average subchronic and chronic emission rates were calculated from equation 1 for each chemical. These calculations and results are summarized in Table A3-2 and Table A3-3 (Parts 1 through 4).

3.0 BOX MODEL

The concentrations of volatile chemicals in air that result from the soil emission pathway were estimated using a simple box model (Hanna et al. 1982). The basic equation is:

$$C = \frac{Q \cdot X}{(H/2) \cdot U} \quad (10)$$

PART 5: CALCULATION OF C VALUES USING BOX MODEL

WIDTH (upwind-downwind distance)	m	W	206.0
AVERAGE WIND SPEED	m/sec	U	2.25
MIXING HEIGHT (Z0 = 0.04m)	m	H	8.7

AIR CONCENTRATION IN BOX (C = Q*W/(H/2)*U)

(6 yr average)	mg/m3	C	8.3E-05	8.7E-06	7.3E-05	3.0E-05	3.0E-06	6.0E-05	1.5E-05	2.3E-05	1.6E-05	2.4E-05
(25 yr average)	mg/m3	C	4.1E-05	4.3E-06	3.6E-05	1.5E-05	1.5E-06	2.9E-05	7.4E-06	1.1E-05	7.7E-06	1.2E-05
(30 yr average)	mg/m3	C	3.7E-05	3.9E-06	3.2E-05	1.3E-05	1.3E-06	2.7E-05	6.8E-06	1.0E-05	7.0E-06	1.1E-05

where:

C = concentration in air (mg/m^3)
Q = emission rate (mg/m^2-sec)
X = cross-wind dimension of the box (m)
H = mixing height of the box (m)
U = average windspeed (m/sec) across the box

Values of these parameters were derived as follows:

E The emission rates were calculated as described in Section 2.0, above.

X The distance from the upwind to downwind edge of the box was estimated to be about 206 m, derived by measurement of the sampling map (Figure 2-1).

H The mixing height of the box is a function of distance from the source and turbulence of the air which, in turn, is a function of the roughness of the terrain. The value of H at the upwind edge of the site is zero. At the downwind edge, the value of H was calculated from the following equation (Pasquill 1975):

$$X = 6.25\ Z_o[(H/Z_o)\ \ln\ (H/Z_o) - 1.58\ (H/Z_o) + 1.58] \qquad (11)$$

where:

X = Upwind to downwind distance (m)
Z_o = Roughness height (m)

The roughness height at the site was estimated to be 0.04 m, based on Cowherd et al. (1985). Employing this value for Z_o and a value of 206 m for X, the corresponding value of H is 8.7 m.

U The average wind speed was taken to be 2.25 m/sec (5.03 mph), based on wind speed measured at the South Bend/St. Joe weather station.

Employing these input parameters, the concentrations of chemicals in air were calculated as shown in Tables A3-2 and A3-3 (Part 5).

APPENDIX 5

EXPOSURE AND RISK CALCULATIONS

USER'S GUIDE

The following pages provide detailed documentation of the exposure and risk calculations performed at this site. The following information may be helpful for those who wish to review these calculations in detail.

Data Input

Data is provided to the computer in three parts. The first part is a worksheet called "POPSUM." This lists all the exposure scenarios that will be evaluated, grouped by populations. This is also where all HIF terms developed in Section 3.0 of this report are entered. The second part is a worksheet named "CTV." This worksheet contains the names of all chemicals of concern, and all available toxicity values. The third part is a series of exposure point concentration ("EPC") tables that record the concentrations of the chemicals of concern at each location. Since concentrations may change over time, three columns exist for each medium: subchronic (C_S), chronic (C_C) and lifetime (C_L) average values. If a chemical is assumed to remain constant over time, all of these values will be equal. These tables repeat the value already documented in Appendix 5.

Exposure and Risk Calculations

Exposure and risk calculations are performed in a series of worksheets (called "WS1," "WS2," etc.), grouped by population (POP1, POP2, etc). Each worksheet is specific for a given population, exposure point, exposure medium and exposure route. All these terms are listed at the top of the page, along with the appropriate HIF values (copied from the POPSUM worksheet). Exposure and risk calculations are then presented below, grouped into three separate sections: subchronic, chronic and lifetime. Within each section, the first data column is for the exposure point concentration, copied from the appropriate EPC table. The next column is for the HIF values. Since this does not depend on the chemical, the same value appears in all rows of the column. The next relevant column is the dose, calculated by multiplying the exposure point concentration by the HIF. The next column is the appropriate chemical, route and duration-specific CTV term (RfD_S, RfD_C and SF for subchronic, chronic and lifetime exposures, respectively). These are copied from the CTV worksheet mentioned above. The last column in each block is the risk estimate. For subchronic and chronic exposures, this is given by the dose or daily intake (DI) divided by the RfD, and is termed the Hazard Quotient (HQ). For lifetime exposures, the value is the excess cancer risk, calculated from the equation

$$RISK = 1 - e^{-(DI_1 \times SF)}$$

In most cases, this value can be accurately estimated simply as the product of $DI_1 \times SF$.

Summary Sheets

After all exposure scenarios that apply to a given population are evaluated, summary tables are prepared that tabulate the dose and risk estimates. These

are copied from the preceding worksheets. The doses are shown in the block on the left, and the risks are shown in the block on the right. In each block, each column represents one exposure scenario. This is identified by the labels heading the column. Finally, risks are summed across chemicals and across pathways. Therefore, caution must be used in summing across the appropriate pathways. These sums are shown just below the individual columns of risk estimates.

Arrangement of This Appendix

Because of the complexity of this site, three series of risk worksheets were necessary to enable calculating risk to all populations. The following lists the summary tables prepared and included in this appendix:

Section	Page
Summary of Critical Toxicity Values	A5-4
1. Current Scenarios (Dirt-Bike Rider, Wader) and Future Workers:	
Exposure Scenarios Evaluated	A5-6
Chemical of Concern	A5-8
Exposure Point Concentrations	A5-10
Exposure and Risk Calculation Worksheets and Summaries	A5-26
2. Hypothetical Future Residential Scenarios (Except for Deep Groundwater):	
Exposure Scenarios Evaluated	A5-100
Chemical of Concern	A5-102
Exposure Point Concentrations	A5-104
Exposure and Risk Calculation Worksheets and Summaries	A5-114
3. Hypothetical Future Residential Scenario (Deep Groundwater Only)	
Exposure Scenarios Evaluated	A5-186
Chemical of Concern	A5-187
Exposure Point Concentrations	A5-189
Exposure and Risk Calculation Worksheets and Summaries	A5-191
4. Background	
Exposure Scenarios Evaluated	A5-215
Exposure Point Concentrations	A5-216
Exposure and Risk Calculation Worksheets and Summaries	A5-218

RANGE NAME: WS3

EXPOSURE AND RISK CALCULATION WORKSHEET

SITE NAME: HIMCO
OPERABLE UNIT: Disk 1
FILE NAME: POP2
LAST UPDATED: 07/24/92

LAND USE: CURRENT
POPULATION: WADER

EXPOSURE POINT: QUARRY PIT
MEDIUM: SEDIMENT
ROUTE: ORAL

HIFs = 1.1E-08
HIFc = 0.0E+00
HIFl = 9.2E-10

RANGE NAME: WS4

EXPOSURE AND RISK CALCULATION WORKSHEET

SITE NAME: HIMCO
OPERABLE UNIT: Disk 1
FILE NAME: POP6
LAST UPDATED: 07/24/92

LAND USE: FUTURE
POPULATION: WORKER (ON)

EXPOSURE POINT: PLANT, ON LANDFIL
MEDIUM: AIR-VOC'S
ROUTE: INHALATION

HIFs = 0.0E+00
HIFc = 6.5E-02

RANGE NAME: WS4

EXPOSURE AND RISK CALCULATION WORKSHEET

SITE NAME: HIMCO
OPERABLE UNIT: DISK 2
FILE NAME: POP2
LAST UPDATED: 07/23/92

LAND USE: FUTURE
POPULATION: RESIDENT CHILD (L)

EXPOSURE POINT: LANDFILL (C)
MEDIUM: GWATER (INH)
ROUTE: INHALATION

HIFs = 1.3E-01
HIFc = 0.0E+00
HIFl = 1.1E-02

RANGE NAME: WS2

EXPOSURE AND RISK CALCULATION WORKSHEET

SITE NAME: HIMCO
OPERABLE UNIT: DISK 2
FILE NAME: POP5
LAST UPDATED: 07/23/92

LAND USE: FUTURE
POPULATION: RESIDENT ADULT (D)

EXPOSURE POINT: DOWNWIND (A)
MEDIUM: AIR-VOC'S
ROUTE: INHALATION

HIFs = 0.0E+00
HIFc = 2.7E-01

RANGE NAME: WS3

EXPOSURE AND RISK CALCULATION WORKSHEET

SITE NAME: HIMCO DUMP SITE
OPERABLE UNIT: BACKGROUND RISK
FILE NAME: POP1
LAST UPDATED: 09/12/91

LAND USE: FUTURE
POPULATION: RES. ADULT

EXPOSURE POINT: HOME(on-site)
MEDIUM: GWATER
ROUTE: DERMAL

HIFs = 0.0E+00
HIFc = 5.9E-02
HIFl = 2.5E-02

APPENDIX 6

EXPANDED TOXICITY SUMMARIES

This appendix contains expanded toxicity summaries for those chemicals that may contribute significant risks above a level of concern at the Himco Dump site.

Section	Chemical	Page Number
1.0	Antimony	A6-3
2.0	Arsenic	A6-4
3.0	Barium	A6-8
4.0	Beryllium	A6-10
5.0	Cadmium	A6-12
6.0	Chromium	A6-15
7.0	Cyanide	A6-18
8.0	Lead	A6-19
9.0	Mercury	A6-21
10.0	Nitrate/Nitrite	A6-25
11.0	Polycyclic Aromatic Hydrocarbons	A6-27
12.0	Vanadium	A6-32

1.0 ANTIMONY

1.1 Noncarcinogenic Effects

Both human occupational and animal studies provide evidence for respiratory effects by antimony compounds following inhalation exposure. Pneumoconiosis has been observed in humans exposed by acute and chronic inhalation to antimony at atmospheric concentrations ranging from 0.08 to 75 mg/m^3 (USEPA 1980). Occupational exposures of 2.15 mg/m^3 antimony as antimony trisulfide have produced increased blood pressure and altered EKG readings in humans (ATSDR 1990). In animals, increased macrophage proliferation and activity, myocardial pulmonary fibrosis and certain types of pneumonia have been observed after inhalation exposure to antimony at concentrations typically ranging from 45 to 125 mg/m^3 (USEPA 1980). To date, the USEPA has not determined an RfC for inhalation of antimony (USEPA 1992).

Oral administration of therapeutic doses of antimony to humans has been associated with nausea, vomiting, skin rashes, myocardial symptoms and hepatic necrosis following ingestion of doses typically ranging from 0.4 to 2.1 mg/kg/day (USEPA 1980). Consistent with observations in humans, animal studies have yielded data showing myocardial damage from oral ingestion of high doses of antimony. A decreased hypotensive response and decreased maternal weight gain have been noted in rats following subchronic oral doses as low as 0.075 mg/kg/day (ATSDR 1990). Schroeder et al. (1970) reported that rats exposed to 5 ppm (0.35 mg/kg/day) of potassium antimony tartrate via drinking water had significantly shortened lifespans, significantly lower glucose levels and significant variations in serum cholesterol levels. This study was the basis on which USEPA (1992) derived a chronic oral RfD of 4E-04 mg/kg/day. A LOAEL of 0.35 mg/kg/day and an uncertainty factor of 1,000 (to account for interspecies and intraspecies variability and the use of a LOAEL) were used to derive the oral RfD. Confidence in the chosen study is rated as low because only one species and one dose level were used, no no-observed-effect level (NOEL) was determined and gross pathology and histopathology were not well described (USEPA 1992).

1.2 Carcinogenic Effects

There is insufficient evidence to determine the carcinogenicity of antimony. Inhalation studies with 4.2 to 36 mg/m^3 antimony trioxide in rats provided only qualitative evidence of lung cancer (USEPA 1980). Other inhalation studies using 3.8 to 4.2 mg/m^3 antimony were negative for carcinogenicity in rats and pigs (ATSDR 1990). Schroeder et al. (1970) administered 5 ppm of potassium antimony tartrate in drinking water to rats from weaning until natural death and concluded antimony was not tumorigenic. Antimony has not been evaluated by the USEPA for evidence of carcinogenic potential (USEPA 1992).

2.0 ARSENIC

Arsenic toxicity depends upon its chemical form. In general, compounds containing As(+3) (arsenites) have somewhat higher acute toxicity than compounds as As(+5) (arsenates) (ATSDR 1991, USEPA 1984). Readily soluble arsenic compounds tend to be somewhat more toxic than poorly soluble forms. However, conversions in valence state and solubility may occur both in the environment and in the body (USEPA 1988), so oxidation state is usually not a critical consideration in evaluating the toxicity of arsenic compounds.

2.1 Noncarcinogenic Effects

Inhalation exposure to arsenic compounds in air can produce skin changes, vascular injury and gastrointestinal irritation, but the effects are usually very mild. The chief effect is usually irritation to the skin and mucous membranes of the eyes, nose and throat (ATSDR 1991). Occupational exposure levels producing these effects range from 0.05 to 0.5 mg/m^3 (ATSDR 1991). For example, skin darkening and corns have been noted in workers who were exposed chronically to airborne levels of about 0.4 mg/m^3 (Perry et al. 1948), while levels of 0.1 to 0.2 mg/m^3 have been reported to cause mild skin irritation (Pinto and McGill 1953). Blom et al. (1985) concluded the risk of neurological effects is minimal at exposure levels of 0.05 mg/m^3, and ATSDR (1991) has estimated that the effects of arsenic in air are minor at exposure levels of 0.1 to 1 mg/m^3. In mice, exposure to 0.5 to 0.9 mg/m^3 produced injury to alveolar macrophages (ATSDR 1991). The USEPA has not developed an inhalation RfC for arsenic (USEPA 1992).

Oral exposure to high doses of arsenic produces marked irritation of the gastrointestinal tract, leading to nausea and vomiting. Symptoms of chronic ingestion of lower levels of arsenic often begin with a vague weakness and nausea. As exposure continues, symptoms become more characteristic and include diarrhea, vomiting, decreased blood cell formation, injury to blood vessels, damage to kidney and liver and impaired nerve function that leads to "pins and needles" sensations in the hands and feet. The most diagnostic sign of chronic arsenic exposure is an unusual pattern of skin abnormalities, including dark and white spots and a pattern of small "corns," especially on the palms and soles (ATSDR 1991)

The average daily intake of arsenic that produces these effects varies from person to person. In a large epidemiological study, Tseng et al. (1968) reported skin and vascular lesions in humans exposed to 0.014 mg/kg/day or more arsenic through the drinking water in Taiwan. These effects were not observed in a control population ingesting 0.0008 mg/kg/day.

The USEPA and the NOAEL of 0.0008 mg/kg/day for skin and vascular lesions (Tseng et al., 1968) to derive an oral RfD of 3.0E-04 mg/kg/day (USEPA 1991). The NOAEL was divided by an uncertainty factor of 3 to account for a lack of reliable data on reproductive effects and the possibility that sensitive human subgroups may not have been identified. Confidence in the RfD is rated medium. A higher rating was not given due to uncertainties in dose estimates and other problems in the epidemiological data base (USEPA 1991).

2.2 Carcinogenic Effects

Lung Cancer

There have been a number of epidemiological studies in humans which indicate that chronic inhalation exposure to arsenic is associated with increased risk of lung cancer (USEPA 1984, ATSDR 1991). As with many epidemiological studies, confounding factors such as smoking and exposure to other lung carcinogens may complicate data interpretation, but the consistent findings among studies constitute convincing evidence that arsenic does increase lung cancer incidence. Increased lung cancer risk has been reported most frequently in smelter workers exposed to predominantly As(+3) (e.g., Lee and Fraumeni 1969). Increased incidence of lung cancer also has been reported in worker populations exposed mainly to As(+5) (Ott et al. 1974). Based on the combined results of five separate risk estimates at two separate smelter facilities, the USEPA 1992 has calculated a geometric-mean unit risk of 4.29E-3 $(mg/m^3)^{-1}$ corresponding to an inhalation slope factor of 15 $(mg/kg/day)^{-1}$.

Skin Cancer

There is strong evidence from a number of human studies that oral exposure to arsenic increases the risk of skin cancer (USEPA 1984, ATSDR 1991). The most common type of cancer is squamous cell carcinoma, which appears to develop from some skin corns. In addition, basal cell carcinoma may also occur, typically arising from cells not associated with the corns. Although these cancers may be easily removed, they can be painful and disfiguring and can be fatal if left untreated.

The amount of arsenic ingestion that leads to skin cancer is controversial. Based on a study of skin cancer incidence in Taiwanese residents exposed mostly to As(+3) in drinking water (Tseng et al. 1968, USEPA 1984), the USEPA has calculated a unit risk of 5E-5 $(\mu g/L)^{-1}$ corresponding to an oral slope factor of 1.75 $(mg/kg/day)^{-1}$ (USEPA 1991). This study has been criticized on several grounds, including uncertainty about exposure levels, possible effects of poor nutrition in the exposed population, potential exposure to other substances besides arsenic and lack of blinding in the examiners.

Consequently, some quantitative uncertainty exists in the cancer potency factor derived from the Tseng data. Nevertheless, these criticisms do not challenge the fundamental conclusion that arsenic ingestion is associated with increased risk of skin cancer, and the Tseng study is considered to be the best study currently available for quantitative estimation of skin cancer risk (USEPA 1988).

Other Cancers

Although the evidence is limited, there are some reports which indicate that chronic oral arsenic exposure may increase risk of internal cancers, including cancer of the liver, bladder and lung (Chen et al. 1985, 1986, 1988a, 1988b). This is supported by limited evidence that inhalation exposure may also increase risk of gastrointestinal, renal or bladder cancers (Lee-Feldstein 1983, Enterline and Marsh 1982a).

Threshold Versus Nonthreshold Model of Arsenic Carcinogenicity

Most carcinogens are considered to act through a nonthreshold mechanism whereby no dose except zero is without risk of cancer. Some researchers have suggested that low doses of arsenic may be partially detoxified by *in vivo* methylation, possibly leading to a threshold dose below which cancer will not occur (Marcus and Rispin 1988). Although there are data which are consistent with this view, the USEPA has reviewed the available information (USEPA 1992) and has concluded that the data are insufficient at present to establish that there is a threshold for arsenic-induced cancer.

2.3 Beneficial Effects

Several studies in animals suggest that low levels of arsenic in the diet may be beneficial for reproduction and normal postnatal development (Schwartz 1977, Anke et al. 1978, 1987, Uthus et al. 1983). However, these studies were not well controlled, and some researchers believe the data are not adequate to show that arsenic is beneficial (Solomons 1984, Hindmarsh and McCurdy 1986). The USEPA (1988) has reviewed the evidence and concluded that the essentiality of low levels of arsenic in animals has not been established but is plausible.

If arsenic is beneficial or essential in animals, it is also likely to be so for humans. Based on the animal data, the estimated beneficial dose for humans is approximately 10 to 50 µg/day (USEPA 1988). This level of arsenic intake is usually provided in a normal diet, and no cases of arsenic deficiency in humans have been reported (ATSDR 1991).

3.0 BARIUM

3.1 Noncarcinogenic Effects

Inhalation exposure to barium has not been extensively studied. One chronic human study was located which indicated the development of a benign pneumoconiosis (baritosis) in several factory workers exposed to barium dusts (ATSDR 1990). However, exposures were not well quantified. Guinea pigs exposed to 0.06 mg/m^3 barium exhibited bronchoconstriction, increased blood pressure and cardiac irregularities (ATSDR 1990). Pulmonary lesions, altered hematological parameters and decreased body weights were observed in rats following inhalation of 3.6 mg/m^3 barium (ATSDR 1990). Exposure of rats to airborne concentrations of 0.8 to 25 mg/m^3 barium for 4 hr/day for four to six months results in a number of adverse effects on body weight, liver function and reproductive parameters (Tarasenko et al. 1977). Based on this study, a chronic inhalation RfD of 1E-4 mg/kg-day has been calculated by USEPA (USEPA 1991). The LOAEL was adjusted for human breathing volume and body weight, and was divided by an uncertainty factor of 1,000 to account for interspecies and intraspecies variability, use of a LOAEL, and for the subchronic exposure duration. This value has not been verified by a USEPA workgroup and is not available in IRIS (USEPA 1991).

Barium ion (Ba^{+2}) interferes with normal potassium ion fluxes in most cells, especially electrically active cells such as nerve and muscle. Ingestion of barium salts may cause acute stimulation of the gastrointestinal muscles, resulting in salivation, nausea, vomiting and diarrhea. Skeletal and cardiac muscles are also stimulated, producing tingling, weakness, hypertension, arrhythmias and electrocardiogram abnormalities (USEPA 1984c, 1987a). Severe cases may be fatal.

The most sensitive index of chronic oral exposure to barium appears to be hypertension (USEPA 1985). In a 10-week study, Wones et al. (1990) did not observe any significant effects on hematological parameters or the cardiovascular system of 11 human subjects following ingestion of 0.21 mg/kg/day barium in the drinking water. Brenniman and Levy (1984) did not detect any significant effects on blood pressure in humans chronically ingesting less than 0.2 mg/kg/day in water. Increased blood pressure has been reported in rats ingesting doses of 0.5 mg/kg/day or higher (Perry et al. 1983). Tardiff et al. (1980) exposed rats to barium at up to 31.5 mg/kg/day for up to 13 weeks with no conclusive signs of barium toxicity observed; however, blood pressure was not measured. The USEPA used the NOAEL of 0.21 mg/kg/day based on the chronic and subchronic human studies by Brenniman and Levy (1984) and Wones et al. (1990) to derive a chronic oral RfD of 7E-2 mg/kg/day (USEPA 1992). The NOAEL was divided by an uncertainty factor of only 3 to account for the subchronic exposure duration of the Wones eat al. 1990 study, since it is supported by the chronic study by Brenniman and Levy (1984). Confidence in the RfD is rated medium since it is supported by more than one human study (USEPA 1991b).

3.2 Carcinogenic Effects

No studies were located describing carcinogenic effects of barium. Two animal studies did not detect any increased tumor incidence following lifetime oral exposure to 0.7 or 0.95 mg/kg/day barium (ATSDR 1990). Barium has not been evaluated by USEPA for human carcinogenic potential (USEPA 1992).

4.0 BERYLLIUM

4.1 Noncarcinogenic Effects

The lung is the main target organ for toxicity following inhalation exposure to beryllium. Exposure to particulate beryllium oxide or to soluble beryllium compounds can result in acute chemical pneumonitis. Chronic exposure to insoluble forms can lead to chronic beryllium disease (berylliosis) in which granulomas develop in the lung. Concentrations of beryllium in the workplace associated with these effects are usually greater than 2 $\mu g/m^3$ (ATSDR 1991). Therefore, the Occupational Safety and Health Administration (OSHA) has set a standard of 2 $\mu g/m^3$ beryllium in the workplace (USEPA 1987).

In animals, the toxic response in the lung following inhalation exposure to beryllium and its compounds is much the same as it is in humans. Exposure to 40 to 4,300 $\mu g/m^3$ beryllium aerosol for 14 to 100 days has produced pulmonary pneumonitis in several animal species. A high mortality rate was noted at the higher concentrations (ATSDR 1991). Reeves et al. (1967) noted inflammatory and proliferative changes in the lungs of rats exposed to 34 $\mu g/m^3$ for 72 weeks. Adverse effects occur in animals at the lowest exposures and because berylliosis may occur in humans at exposure levels lower than the chronic animal LOAEL of 34 $\mu g/m^3$ (Reeves et al. 1967). The USEPA has not developed an inhalation RfC for beryllium due to insufficient data.

Only limited data exist on the effects of oral exposure to beryllium. Subchronic oral doses of 4.4 mg/kg/day produced a number of pathological disturbances in the lungs of rats, including a harder, more opaque appearance and increased enzyme activities (ATSDR 1991). Schroeder and Mitchener (1975) did not observe any adverse noncarcinogenic effects in rats given 5 ppm (0.54 mg/kg/day) beryllium in the drinking water for life, although the lungs were not examined. The USEPA used this study to derive an oral RfD of 5E-3 mg/kg/day (USEPA 1992). The NOAEL of 0.54 mg/kg/day was divided by an uncertainty factor of 100 to account for interspecies and intraspecies variability. Confidence in this value is rated low since only one dose was tested and the data base was considered to be of low to medium quality (USEPA 1992).

4.2 Carcinogenic Effects

Wagoner et al. (1980) conducted an epidemiological study on cancer incidence in 2,000 workers employed in beryllium processing activities. Increased mortality from lung cancer was observed. Expected lung cancer deaths (adjusted for smoking) were estimated to range from 13 to 14, in comparison to the 20 observed. Considerable uncertainty existed in the workplace beryllium concentration and the actual duration of exposure. Pulmonary carcinomas have been observed in rats and monkeys following exposures as low as 36 $\mu g/m^3$ (ATSDR 1991). The USEPA, recognizing the inadequate and limited data base, has calculated a slope factor of 8.4 $(mg/kg\text{-}day)^{-1}$ for beryllium by the inhalation route based on the human study by Wagoner et al. (1980) (USEPA 1992).

Evidence for the carcinogenicity of beryllium by the oral route comes from a single drinking water study in rats. Schroeder and Mitchener (1975) reported an elevated incidence of gross tumors in male rats exposed to 5 ppm beryllium in water when all tumor sites were combined. The USEPA used this study as the basis for an oral slope factor of 4.3 $(mg/kg\text{-}day)^{-1}$ (USEPA 1992). Beryllium is classified as a B2 carcinogenic, probable human carcinogen (USEPA 1992).

5.0 CADMIUM

5.1 Noncarcinogenic Effects

Acute inhalation exposures to 9 to 50 mg/m^3 cadmium for one to five hours have produced fatalities in humans. Lower concentrations of 0.2 to 0.5 mg/m^3 can produce mild reversible signs of metal fume fever (ATSDR 1989). A large number of epidemiological studies have reported renal, pulmonary and hematological effects associated with chronic occupational exposures to cadmium. Air concentrations typically ranging from 0.020 to 0.270 mg/m^3 have produced tubular protinuria, kidney lesions, emphysema and anemic in chronically exposed workers (Bonnell 1955, Kjellstrom et al., 1977; Lauwerys et al. 1974); Materne et al. 1975; Tsuchiya 1967). Based on the review of several epidemiological studies, the World Health Organization (WHO 1980) estimated a 20-year exposure NOAEL of 0.007 mg/m^3 for cadmium. In animals, lung fibrosis and emphysema have been reported in rats and rabbits after subchronic exposure to 0.3 and 5 mg/m^3 cadmium, respectively (ATSDR 1989).

The USEPA is currently reviewing an inhalation RfC for cadmium and is listed as pending (USEPA 1992). The ATSDR has derived an inhalation Minimal Risk Level (MRL) of 7E-4 mg/m^3 (ATSDR 1989). This value is based on the estimated NOAEL of 7E-3 mg/m^3 (WHO 1980) for renal effects in humans, and was divided by an uncertainty factor of 10 to account for intrahuman variability (ATSDR 1989).

Acute oral dose of 20 to 130 mg/kg cadmium have been reported to be lethal to humans. Doses as low as 0.04 can produce gastrointestinal distress in humans. As with inhalation exposures, the kidney is the primary target for ingested cadmium. The renal sensitivity to cadmium stems from its ability to accumulate to high concentrations at the renal cortex, impairing renal function. The chief sign is proteinuria, but severe cases can produce electrolyte imbalance and demineralization of the bone (ATSDR 1990). Post-mortem and *in vivo* measurements are in agreement with a critical concentration of 200 µg cadmium/wet weight renal cortex, above which is associated with significant proteinuria (ATSDR 1980). In Japan, Yemagata and Shigematsu (1970) estimated a LOAEL of 0.008 mg/kg/day for proteinuria and bone disorders from intake of cadmium in rice. In mice and rats, subchronic and chronic oral administration of cadmium at doses typically ranging from 0.1 to 5 mg/kg/day have resulted in a variety of effects including a suppression of the immune system, increased mortality, decreased reproduction, developmental effects, bone mineral changes, hypertension and damage to the kidney and heart (ATSDR 1989). Liver changes were reported in rabbits following doses of 0.013 mg/kg/day for 200 days (Stowe et al. 1972).

The USEPA has calculated an oral RfD of 5E-4 and 1E-3 mg/kg/day for cadmium in water and food, respectively (USEPA 1992). The USEPA derived NOAELs of 0.005 (water) and 0.01 (food) mg/kg/day for cadmium based on a toxicokinetic model that assures 2.5% absorption from food, 5% absorption from water, 0.01% elimination of cadmium body burden/day and the critical value of 200 µg cadmium/gram wet weight renal cortex (USEPA 1985a). The NOAELs were divided by an uncertainty factor of 10 to account for intrahuman variability. Confidence in these values is rated high since they are based on data from numerous human and animal studies, and the model includes all relevant pharmacokinetic parameters (USEPA 1992).

5.2 Carcinogenic Effects

Epidemiological studies have revealed limited evidence for an excess risk of lung cancer in cadmium-exposed workers. Thun et al. (1985) reported a two-fold excess risk of lung cancer in cadmium smelter workers exposed to 170 to 2,500 µg/m^3 for six months or more. Several other studies have also indicated increased risks for lung cancer or prostate cancer. However, these studies are limited due to a small number of cases and exposure to other chemicals. In rats, inhalation of 12.5 to 50 µg/m^3 for 18 months produced a dose-dependent increase in lung tumors (Takenaka et al. 1983). Intratracheal instillation studies have also reported increased tumor incidences in the mammary gland and prostate in rats (ATSDR 1989; USEPA 1985b). The USEPA (1992) has calculated an inhalation unit risk of 1.8E-3 (µg/m^3)$^{-1}$ corresponding to a slope factor of 6.3E+0 (mg/kg/day)$^{-1}$ based on the lung cancer data in smelter workers (Thun et al. 1985). Although the use of animal data would result in a higher (and therefore, more conservative) slope factor, USEPA concluded it was more appropriate to use the data from Thun et al. (1985) to avoid complications due to species variation and type of exposure (cadmium salt versus cadmium fume or oxide).

Mortality studies in humans and carcinogenicity studies in animals have not detected any increased cancer incidences following oral exposure to cadmium (ATSDR 1989; USEPA 1985b). The USEPA has not derived an oral slope factor for cadmium (USEPA 1992).

5.3 Beneficial Effects

Animals fed low-cadmium diets were reported to have depressed growth, impaired reproduction and other effects (NAS 1989). The Food and Nutrition Board considers the evidence for cadmium essentiality to be weak, and if they exist, are probably met by the typical daily intake of 0.0004 mg/kg/day in the diet (ATSDR 1989; NAS 1989).

6.0 CHROMIUM

Chromium exists in the environment mainly as salts of Cr(III) and as oxy-compounds of Cr (VI). The toxicity of Cr(III) is less than for Cr(VI), so these two forms are discussed separately.

6.1 Noncarcinogenic Effects

Chromium (III)

Data concerning the toxicity of inhaled Cr(III) in humans were not located. Little data are available describing adverse effects in animals following inhalation exposures to Cr(III). Johansson et al. (1986) reported a decrease in phagocytic activity in macrophages in rabbits exposed via inhalation at 600 $\mu g/m^3$ Cr(III) [$Cr(NO_3)_3$] for four to six weeks. ATSDR (1989) considers this value to be a LOAEL for intermediate Cr(III) exposure. There is no inhalation RfD for Cr(III) at this time (USEPA 1992).

Data concerning the toxicity of ingested Cr(III) in humans were not located. Oral exposures to Cr(III) compounds are not associated with significant toxicity except at vary high doses. In rats, acute oral LD_{50} values range from 600 to 2,600 mg Cr(III)/kg. Chronic exposure of rats to water containing 25 mg Cr(III)/L (2.4 mg/kg/day) for one year resulted in no detectable adverse effects (USEPA 1985, 1987). No treatment related effects were reported for rats exposed to doses up to 1,468 mg Cr(III)/day in the diet for two years (Ivankovic and Preussmann 1975). However, in the subchronic portion of this study, the dose level of 1,468 mg/kg/day for 90 days produced decreased liver and spleen weights in rats. The chronic NOAEL of 1,468 mg/kg/day was used to derive an oral RfD of 1E+0 mg/kg/day (USEPA 1992). The NOAEL was divided by an uncertainty factor of 100 to account for interspecies and intraspecies variability, and an additional modifying factor of ten was used to account for uncertainty in the NOAEL since the same value was reported as a LOAEL in the 90-day study. Confidence is rated low due to lack of experimental protocol in the critical study and a lack of supporting data (USEPA 1992).

Chromium (VI)

The respiratory tract is a target of intermediate and chronic inhalation exposure to chromium. Many cases of nasal mucosal ulceration and nasal septal perforation have been reported in persons occupationally exposed to Cr (VI). Lindberg and Hedenstierna (1983) reported that evidence of adverse nasal effects were found at mean exposure levels of 2 to 200 $\mu g/m^3$ Cr (VI) but not at <1 $\mu g/m^3$ Cr (VI). That a concentration of about 2 $\mu g/m^3$ is an effect level is supported by the Kuperman (1964) study which reported nasal irritation in sensitive individuals at a concentration of 2.5 to 4 $\mu g/m^3$. Because the nasal effects observed in the Lindberg and Hedenstierna (1983) study at concentrations <0.2 $\mu g/m^3$ were mild and no effects were observed at <1 $\mu g/m^3$, a concentration of 1 $\mu g/m^3$ is considered a NOAEL for nasal effects (ATSDR 1989). In animals, respiratory tract effects such as nasal mucosa perforation, granulomata of the lungs, bronchial epithelial necrosis and alveolar proteinosis have been reported in several species following exposures typically

ranging from 1,600 to 4,300 $\mu g/m^3$ Cr(VI). Immune system depression was apparent in rats after exposure to 200 $\mu g/m^3$ Cr(VI) for 90 days (ATSDR 1989). Using the LOAEL of 0.002 mg/m^3 as described by Lindberg and Hedenstierna (1983), USEPA (1991) derived a chronic inhalation of RfC of 2E-6 (5.7E-07 mg/kg/day). The LOAEL was adjusted for continuous exposures divided by an uncertainty factor of 300 to account for interhuman variability, use of a LOAEL and the subchronic duration of the study. This value has been verified and its input in IRIS is pending (USEPA 1991).

By the oral route, Cr (VI) is somewhat more toxic than Cr(III), with an oral LD_{50} (as $Na_2Cr_2O_7$) in rats of 20 mg/kg. However, detrimental effects from long-term ingestion of low levels of Cr(VI) have not been observed (USEPA 1987, 1985). Chronic ingestion of water containing 1 mg/L of Cr(VI) over a three-year period did not produce any adverse health effects in a Long Island family drinking from a private well (USEPA 1985). Nausea was the only effect observed in an individual consuming a 10 ppm solution of Cr(VI) for 15 days (ATSDR 1989). No adverse health effects were observed in rats following the ingestion of Cr(VI) in drinking water at 14.4 mg/kg-day for 60 days (USEPA 1985). Female dogs administered potassium chromate (K_2CrO_4) in their drinking water at 11.2 mg Cr(VI)/L for four years showed no abnormalities in physical condition, food consumption or growth rate. Sprague-Dawley rats administered water containing K_2CrO_4 at concentrations up to 25 mg Cr(VI)/L (2.4 mg/kg/day) for one year exhibited no pathologic effects (MacKenzie et al. 1958). This study in rats was used to calculate a chronic oral RfD of 5.0E-03 for Cr(VI) (USEPA 1992). The NOAEL of 2.4 mg/kg/day was divided by an uncertainty factor of 100 to account for interspecies an intraspecies variability. Confidence in this value rate is low due to the small number of animals used and parameters measured in the critical study, and the supporting studies are also of low quality (USEPA 1992).

6.2 Carcinogenic Effects

Chromium (III)

No evidence has been reported that Cr(III) is carcinogenic following either inhalation or ingestion (ATSDR 1989). Chromium (III) has not been evaluated by EPA for human carcinogenic potential (USEPA 1992).

Chromium (VI)

Results of several epidemiologic studies consistently link inhalation of Cr (VI) to increased incidences of lung tumors (USEPA 1992). Some of these studies, however, did not attempt to determine between exposures to Cr III or Cr VI but there is sufficient evidence in other occupational studies to attribute the carcinogenic potential to Cr (VI).

Sufficient animal data also exist to conclude that Cr (VI) is carcinogenic by a number of routes (intramuscular injection site tumors, intrapleural implant site tumors, intrabronchial implantation site tumors and subcutaneous injection site sarcomas (USEPA 1992)).

Chromium (VI) has been assigned a weight-of-evidence classification of A (a human carcinogen) by the inhalation route (USEPA 1992). An inhalation unit risk of $1.2E-2$ $(\mu g/m^3)^{-1}$ corresponding to a slope factor of 4.1E+01 $(mg/kg\text{-}day)^{-1}$ was calculated by USEPA from available epidemiological studies that indicate a dose-response relationship between Cr(VI) and lung cancer. There is no convincing evidence that oral exposure to Cr(VI) is carcinogenic (USEPA 1987).

6.3 Beneficial Effects

Chromium (III) produces beneficial effects when administered to animals fed a chromium deficient diet. Beneficial effects include enhanced glucose uptake, decreased blood cholesterol levels and increased life span. An estimated safe and adequate human intake for Cr(III) of 50 to 200 µg/day has been calculated by the National Academy of Sciences (NAS 1989). The average daily intake of chromium in the U.S. is about 60 to 100 µg/day, mostly in food.

7.0 CYANIDE

7.1 Noncarcinogenic Effects

Cyanide is a general cellular poison which acts by binding in place of oxygen to heme-containing enzymes. In particular, cyanide binds to mitochondrial cytochrome oxidase, thereby blocking the cell's ability to oxidize metabolites and generate energy. Many tissues are affected by exposure to cyanide, but the nervous system is usually the most sensitive. Symptoms of acute cyanide toxicity include a dry burning throat, suffusing warmth, rapid breathing, gasping, tremors and convulsions.

7.1.1 Inhalation Exposure

Information on the effects of inhalation exposure to cyanide is limited. Concentrations of 100 to 500 ppm in air are fatal to humans within 10 to 60 minutes (Hartung 1981). Chronic exposure of humans to cyanide in the workplace has been associated with thyroid abnormalities (El Ghawabi et al. 1975) and increased incidence of nonspecific symptoms such as headache and nausea (Blanc et al. 1985). The USEPA has not determined an RfC or RfD for inhalation exposure to cyanide (USEPA 1991b).

7.1.2 Oral Exposure

The fatal oral dose in humans ranges from 0.5 to 2.9 mg CN/kg (USEPA 1987). However, dose-response data are lacking on nonlethal effects of oral exposure in humans. In rats, a two-year dietary study did not detect any significant adverse health effects at doses up to 10.8 mg CN/kg-day (Howard and Hazal 1955). In another study, rats consuming 30 mg CN/kg-day for one year had myelin and thyroid degeneration as well as weight loss (Philbrick et al. 1979). Based upon the NOAEL of 10.8 mg CN/kg-day from the Howard and Hazal study, the USEPA has calculated a chronic oral RfD for cyanide of 2E-2 mg/kg-day. The NOAEL was divided by an uncertainty factor of 100 to account for interspecies and intraspecies variation, and by a modifying factor of 5 to account for the apparent tolerance to cyanide observed when administered with food. The USEPA has medium confidence in this value (USEPA 1991b). The RfD is also considered to be suitable for evaluating subchronic oral exposure to cyanide (USEPA 1991a).

7.2 Carcinogenic Effects

No human or animal data were located regarding the carcinogenic potential of cyanide (ATSDR 1988). The USEPA (1991b) has assigned cyanide a weight-of-evidence classification of D (not classifiable) based on the fact that pertinent information regarding potential carcinogenic effects of cyanide were not located in the available literature.

8.0 LEAD

8.1 Noncarcinogenic Effects

Lead is a heavy metal that produces a number of adverse health effects in humans. Acute and subacute poisoning generally occurs only after ingestion of large doses of lead (in excess of 1,000 mg/day) (NAS 1977). Encephalopathy is typically the most significant clinical manifestation, sometimes occurring

quite suddenly. Signs of developing central nervous system impairment include apathy, stupor, hyperirritability, depression, headache and tremor. Other tissues that may be injured include the gastrointestinal tract, the liver, the kidneys and red blood cells (USEPA 1986).

Instances of short-term lead poisonings in humans are now rather rare, and most health concerns center around chronic low-level exposure. Lead is retained strongly in exposed humans, and lead toxicity is cumulative. One of the characteristic effects of chronic lead exposure is hypochromic microcytic anemia, stemming from lead-induced inhibition of heme biosynthesis and a decrease in erythrocyte lifespan. Heme synthesis is inhibited not only in erythrocytes but in other tissues as well, and several key heme-containing enzymes (e.g., those required to synthesize vitamin D) show decreased activity following lead exposure (USEPA 1986).

Chronic exposure also results in impairment of the nervous system. Many studies have shown that animals and humans are most sensitive to the effects of lead during the time of nervous system development. Thus, the fetus, infants and young children are particularly vulnerable. Symptoms of nervous system damage range from subtle decreases in intelligence and scores on neurological tests to frank encephalopathy. Effects on the nervous system are generally considered to be irreversible (USEPA 1986). Additionally, lead exposure during pregnancy may result in decreased size and growth of the infant and may increase the chances of premature birth or other complications during pregnancy (USEPA 1986).

Recent studies have focused attention on the cardiovascular system as a target for lead. Epidemiological data from the United States reveal a strong correlation between blood pressure and the level of lead in the blood. Although the changes in blood pressure associated with moderate lead exposures are small, the increased risk of stroke or heart attack make this an effect of concern (USEPA 1986).

It is currently difficult to identify what degree of lead exposure, if any, can be considered safe. Most studies in humans do not involve measurement of actual exposure; instead, exposure is judged by measurement of blood lead (PbB) values. Subtle signs of lead-induced effects begin to be apparent at around 10 µg/dL or even lower, with effects becoming clearer by 3,040 µg/dL. Frank clinical signs of lead toxicity are usually apparent at blood lead levels of 80,100 µg/dL. Of special concern is the claim by several researchers that some of the effects of lead (neurobehavioral effects, heme synthesis, fetal development) do not have a threshold value (USEPA 1986).

The daily exposure to lead that produces these PbB levels cannot presently be calculated with a high degree of certainty, but it seems likely that inhalation or ingestion of only small amounts of lead per day could be of concern. Based on this, the USEPA (1988) has established a Maximum Contaminant Level Goal (MCLG) of zero for lead in drinking water. Although there is no agreed upon PbB level considered to be "safe," the USEPA has identified the range of 10 to 15 µg/dL as a range of concern for effects that warrant avoidance. USEPA has also developed a biokinetic model that predicts

the expected distribution of PbB values in populations of children exposed to various lead sources (USEPA 1989). USEPA has decided it is inappropriate to derive an RfD because some effects occur at levels so low as to be essentially without a threshold (USEPA 1992).

8.2 Carcinogenic Effects

Studies in animals indicate that chronic oral exposure to very high doses of lead salts may cause an increased frequency of tumors of the kidney (USEPA 1986). However, there is only limited evidence that lead is carcinogenic in humans, and the noncarcinogenic effects on the nervous system and on hematopoiesis are usually considered to be the most important and sensitive endpoints of lead toxicity (USEPA 1988). USEPA has classified lead as a Group B2, probably human carcinogen, based on sufficient information from animal studies with inadequate information on humans (USEPA 1992). However, slope factors for inhalation or oral exposure to lead have not been developed.

9.0 MERCURY

The type and severity of effects from mercury ingestion are dependent on the form in which it is administered (organic versus inorganic). Therefore, these two forms will be addressed separately, below.

9.1 Noncarcinogenic Effects

Inorganic mercury (inhalation) - A few fatalities have occurred following exposure to high (unspecified air concentrations of inorganic mercury. Death was attributed to a loss of respiratory function due to extensive pulmonary tissue damage (edema, pneumonia and epithelial desquamation). Workers exposed

to concentrations of 1 to 44 mg/m^3 inorganic mercury have developed chest pains, dyspnea, cough, hemoptysis, impaired pulmonary function and pneumonitis. One study reported a significant negative association between diastolic blood pressure and inorganic mercury exposure in humans. However, other studies reported an increase in blood pressure following acute exposures. Gastrointestinal symptoms such as nausea, vomiting, diarrhea, gingivitis and mercurial stomatitis are also associated with the inhalation of inorganic mercury vapor. Human case studies have revealed that the inhalation of inorganic mercury can produce mild hepatic effects (biochemical changes) and renal effects (increased creatinine excretion, proteinuria, hematuria and degeneration of the convoluted tubules). Concentrations of 1.0 mg/m^3 have produced erythematous and pruritic skin rashes, burning eyes and conjunctivitis. Short-term exposures to 44 mg/m^3 produce long lasting feelings of irritability, a lack of ambition and a lack of sexual desire.

Other neurological symptoms such as tremors, erethism, decreased motor functions, slowed peripheral nerve conduction, impaired reflexes, headaches, and abnormal EEGs are also associated with exposure to inhaled inorganic mercury (ATSDR 1989). A few human case studies also suggest that prenatal exposure to mercury vapor can produce menstrual alterations and increased spontaneous abortions (ATSDR 1989).

Workers at chlor-alkali factories are chronically exposed to inorganic mercury vapor. Renal effects occur at concentrations of approximately 0.1 mg/m^3. The first symptoms are mild (such as proteinuria) and are reversible. More severe damage is indicated by glomerular dysfunction, nephrotic syndrom and edema. These effects usually subside a few months after the exposure ceases. Workers exposed to inorganic mercury vapor typically complain of muscle pain, burning feet, muscle cramps, and develop a yellow haze on their lenses. Neurotoxicity (as evidenced by tremors, erethism, decreased nerve conduction velocity, impaired performance and psychomotor skills) is the critical effect for inhalation exposure to inorganic mercury (Fawer et al. 1983; Piikivi and Tolonen 1989; Piikivi and Hanninen 1989; Piikivi 1989). These studies identified a NOAEL of 0.009 mg/m^3 for neurological effects of inorganic mercury.

In rats and rabbits, histopathological changes of the kidney have been reported following subchronic inhalation exposures to 0.9 to 3 mg/m^3 inorganic mercury. Necrosis of the kidney, liver and heart has also been observed in rabbits after inhalation of 0.9 to 6 mg/m^3 mercury. The same dose range has also produced neurological effects including tremors and histopathological changes and necrosis of the brain. Pigeons exhibited abnormal behavior after subchronic exposure to 17 mg/m^3 (ATSDR 1989).

The USEPA has derived an inhalation administered RfC of 3E-4 mg/m^3 for inorganic mercury (USEPA 1991a). This value is based on the NOAEL of 0.009 mg/m^3 for neurological effects in humans as described by several studies (Fawer et al. 1983; Piikivi and Tolonen 1989; Piikivi and Hanninen 1989; Piikivi 1989). The NOAEL was divided by an uncertainty factor of 30 to derive the RfC. This RfC value has been verified by a USEPA workgroup, and IRIS input is pending.

Organic mercury (inhalation) - Human fatalities have been reported following exposure concentrations as low as 1 mg/m^3 diethyl mercury for 4 to 5 months (ATSDR 1989). There is limited evidence that inhalation exposure of rats to 0.5 to 2.5 mg/m^3 inorganic mercury to rats can cause a decrease in the number of living fetuses and an increase in the number of congenital malformations and resorptions (ATSDR 1989). The USEPA has not derived an inhalation RfC or RfD for organic mercury (USEPA 1991b).

Inorganic mercury (ingestion) - Oral doses of 29 to 50 mg/kg of inorganic mercury have produced fatalities in humans. Death is attributed to shock, cardiovascular collapse, renal failure and severe gastrointestinal damage. Therapeutic administration of mercury salts (for its diuretic and antiseptic properties) has resulted in nephrotic syndrome (albuminuria, hypoalbuminemia, edema and hypercholesterolemia) after a single dose of 21.4 mg/kg. Renal failure and neurological effects, including a decreased brain weight and a decreased cerebellar cell number, were reported in two human case studies involving the consumption of 3.4 mg/kg/day mercurous chloride for 6 to 25 years in the form of a laxative pill (ATSDR 1989).

In animals, subchronic oral exposure to inorganic mercury has produced effects on the renal, immunological and neurological systems. Degenerative changes to the neurons of the dorsal route ganglia and cerebellar granule cells accompainied by ataxia, sensory loss and decreased body weight were noted in rats given oral doses of 0.8 mg/kg/day mercury as mercurous chloride for 1 to 11 weeks. A suppression of the lymphoproliferative response has been reported in mice following ingestion of 2.1 mg/kg/day for 7 weeks. Several oral and parental studies on Brown-Norway rats identify 0.3 mg/kg/day as the LOAEL for the renal effects (glomerulonephritis) of inorganic mercury (Druet et al. 1978; Bernaudin et al. 1981; and Andres 1984). There is sufficient evidence to indicate that the renal damage is mediated through an immune-type mechanism (ATSDR 1989). Pregnant hamsters given a single dose of 31.4 mg/kg inorganic mercury had an increased percentage of fetal resorptions compared to unexposed hamsters (ATSDR 1989).

The USEPA has derived an oral administered RfD of 3E-4 mg/kg/day for inorganic mercury (USEPA 1991a,c). This value is based on the LOAEL of 0.3 mg/kg/day for renal effects in Brown-Norway rats identified by several studies (Druet et al. 1978; Bernaudin et al. 1981; Andres 1984). The LOAEL was divided by an uncertainty factor of 1,000 (10 for interspecies variability, 10 for intrahuman variability, and 10 for the use of a LOAEL) to derive the RfD. This RfD has been verified by a USEPA workgroup, however, its input into IRIS is still pending (USEPA 1991a).

Organic mercury (ingestion) - The nervous system is the primary target for the effects of orally administered organic mercury. In addition, organic mercury can also produce effects on the renal and cardiovascular systems. Estimated doses, based on tissue concentrations in human fatality cases, range from 10 to 60 mg/kg/day. Abnormal renal function (polyuria, polydypsia and albuminuria) were reported in humans following ingestion of ethyl mercury.

Consumption of methylmercury in contaminated fish or grain has produced a variety of neurological symptoms in humans, including tingling extremities, impaired senses, slurred speech, incoordination, weakness, memory loss, depression, insomnia and death due to central nervous system failure (ATSDR 1989).

In rats, renal effects (tubular damage, fibrosis and inflammation) have been reported after oral exposure to 0.08 to 0.84 mg/kg/day organic mercury for 1 to 12 weeks, and at 0.015 mg/kg/day for chronic exposures. An increase in systolic blood pressure was noted in rats given 0.4 mg/kg/day organic mercury by gavage for 3 to 4 weeks. Animal studies have revealed that methyl mercury is a more potent neurotoxin than inorganic mercury. Neurological effects (degenerative changes, particularly in the cerebellum, behavioral changes, depressed dopamine synthesis) were reported in cats and mice at doses ranging from 0.015 to 0.8 mg/kg/day, and in rats at doses ranging from 0.7 to 3.2 mg/kg/day organic mercury (ATSDR 1989). Impaired spatial vision, reduced visual sensitivity, intention tremors, somesthetic impairment and incoordination were noted in monkeys given 0.04 to 0.48 mg/kg/day for 3 to 4 years (ATSDR 1989). Developmental effects including fetal eye anomalies, neurotoxicity, and behavioral changes have been reported in the offspring of rats exposed to doses of 0.008 to 0.25 mg/kg/day organic mercury during gestation. Signs of fetotoxicity, fetal death and decreased male fertility have been noted in mice and rats at doses ranging from 1 to 5 mg/kg/day organic mercury (ATSDR 1989).

The USEPA has not derived an oral RfD for organic mercury (ATSDR 1991b).

9.2 Carcinogenic Effects

Data concerning the carcinogenicity of inhaled or ingested mercury (organic or inorganic) in humans were not located in the literature cited in the reference section. Limited animal studies do not indicate any carcinogenic effect for mercury. The USEPA has classified mercury as Group D, not classifiable as to human carcinogenicity (USEPA 1991b).

9.3 Beneficial Effects

The Food and Nutrition Board does not recognize mercury as an essential trace mineral, and no recommended dietary allowance has been established (FNB, 1989).

10.0 NITRATE/NITRITE

Nitrate and nitrite are naturally occurring inorganic ions. Nitrate can be converted to nitrite in the body, particularly by bacteria in the alimentary canal. Therefore, the effects of these two ions are discussed together.

10.1 Noncarcinogenic Effects

Data concerning the toxicity of inhaled nitrate or nitrite in humans or animals were not located.

Studies in humans and animals indicate that the chief adverse effect of nitrate and nitrite is the production of methemoglobinemia. Nitrate must first be converted to nitrite to produce this effect. Nitrite oxidizes the Fe^{+2} form of iron in hemoglobin to Fe^{+3}, forming methemoglobin. Methemoglobin can not bind oxygen normally, therefore the oxygen-carrying capacity of the blood is reduced. Typical blood levels of methemoglobin range from 0.5 to 2%. Levels below 10% are not associated with any adverse effects. Levels above 10% may result in cyanosis whereas levels as high as 25% can produce weakness, rapid pulse and tachypnea (USEPA 1991).

Infants appear to be particulary sensitive to the methemoglobin-forming effects of nitrate. This sensitivity is due to a higher pH in the stomach of infants which allows for a larger bacteria population (USEPA 1990). Bosch et al. (1950) evaluated 139 cases of cyanosis in children (8 days to 5 months old) caused by nitrate contaminated wells. All wells contained greater than 10 mg/L nitrate-nitrogen. In 214 cases of infantile methemoglobinemia, Walton et al. (1951) reported all were due to consumption of water with levels of 11 mg/L or more nitrate-nitrogen. Based on estimates of accidental exposures, older children and adults require doses of 8 to 12 mg/kg nitrite-nitrogen to produce methemoglobinemia (USEPA 1990). Two epidemiological studies reported an increased risk of birth defects (2.3 to 2.8) in subpopulations with elevated levels of nitrate in the drinking water (5 to 15 mg/L and 1.3 to 26 ppm) (USEPA 1990).

In rats, oral doses of 40 to 80 mg/kg/day nitrate or nitrite-nitrogen resulted in methemoglobinemia. Pregnant rats may be more susceptible since a single dose of 0.5 to 6 mg/kg nitrite-nitrogen was sufficient to produce up to 60% methemoglobin (USEPA 1990). Altered thyroid weight and function has been observed in rats and pigs at higher doses of nitrate-nitrogen. Nitrite has also produced a reduction in life span and damage to the liver, lung, spleen, kidney and adrenals of mice or rats (USEPA 1990). In general, doses of 2 to 10 mg/kg/day nitrite-nitrogen did not result in ay developmental or reproductive effects in animals. However, higher doses (12 to 90 mg/kg/day nitrite-nitrogen) have resulted in decreased reproduction and sperm abnormalities in the parents, and increased mortality, decreased body weight, liver and spleen damage and anemia in their offspring. A few studies have noted behavioral changes in the offspring at doses as low as 1.7 mg/kg/day nitrate-nitrogen or 2.5 mg/kg/day nitrite-nitrogen (USEPA 1990).

The USEPA has calculated an oral RfD of 1.6E+0 mg/kg/day for nitrate-nitrogen and 1E-1 mg/kg/day for nitrite-nitrogen (USEPA 1991). These values are based on the NOAEL of 10 mg/L nitrate-nitrogen for infantile methemoglobinemia as reported by Bosch et al. (1950) and Walton (1951). The NOAEL was adjusted for daily water intake (0.64-1 L) and infant body weight (4 to 10 kg). The use of an uncertainty factor was not necessary since the critical studies identified the NOAEL in the most sensitive human subpopulation, however, a modifying factor of 10 was used for nitrite-nitrogen to account for the direct toxicity of nitrite. Confidence in these values is rated high since there are a large number of good supporting human and animal studies (USEPA 1991).

10.2 Carcinogenic Effects

By themselves, studies on the carcinogenicity of nitrate or nitrite have been negative or equivocal. The primary reason for concern regarding carcinogenicity lies in the ability of the nitrite to react with secondary and tertiary amines (commonly found in the diet) to form carcinogenic nitroamines. A number of animal studies have shown that nitrite, when fed concurrently with a nitrosatable amine, yields an increased incidence of tumors in a number of tissues including the lungs, esophagus, stomach, tongue, nasal cavity and liver (USEPA 1990). A carcinogenicity assessment is currently listed as pending in IRIS (USEPA 1991).

11.0 POLYCYCLIC AROMATIC HYDROCARBONS

Polycyclic or polynuclear aromatic hydrocarbons (PAHs) are a broad class of related compounds characterized by the presence of two or more fused aromatic rings. Individual PAHs vary considerably in their chemical structure, and differences in toxicity or potency exist among different compounds.

11.1 Noncarcinogenic Effects

Data on noncancer effects in humans following exposure to PAHs are mainly limited to obsevations following exposures to naphthalene. Based on case studies in infants, children, and adults, the primary health effect of naphthalene appears to be hemolytic anemia (ATSDR 1990a). This effect has been noted following inhalation, oral and dermal exposures, but dose response data are not available. Other noncancer effect of naphthalene which have been reported in humans exposed by the oral and/or inhalation routes include gastrointestinal distress, confusion, jaundice, renal disease and cataracts (ATSDR 1990a). Direct dermal contact with napthalene may cause regressive venucae (Cottini and Mazzone 1939, Rhoads et al. 1954).

Based on case reports of infants, children and adults, hemolytic anemia is the primary health concern for humans exposed to naphthalene (ATSDR 1990). This effect has been reported following exposure by inhalation, ingestion and dermal absorption, but dose response data were not available.

In animals, hemolytic effects were not observed in rats or mice exposed to naphthalene (Shopp et al. 1984) but were observed in dogs (Zuelzer and Apt 1949). Hepatic effects, including increased liver weight and enzyme activity, were reported in rats administered naphthalene at orally at doses of 1,000 mg/kg-day (Rao and Pandya 1981). Plasterer et al. (1985) reported a decrease in the number of live pups per litter in mice dosed with 300 mg/kg-day naphthalene in corn oil during pregnancy. Cataracts were observed in rabbits

and rats after oral administration of naphthalene at 1,000 mg/kg-day (Yamauchi et al. 1986, Rossa and Pau 1988). In a subchronic (90-day) oral study in rats, NTP (1980) identified a NOAEL for naphthalene of 35.7 mg/kg-day. This value is strongly supported by a NOAEL of 41 mg/kg-day identified in a chronic oral exposure study in rats (Schmahl 1955). Based on the NOAEL of 35.7, the USEPA has derived an oral RfD for naphthalene of 4E-03. This was calculated using an uncertainty factor of 10,000. Confidence in the value is considered to be medium (IRIS 1991).

The USEPA has derived oral RfD values for several other PAHs based on 90-day studies in mice (USEPA 1988, 1989b, 1989c, 1989d, 1989e). The effects noted included hepatotoxicity (300 mg/kg/day of acenaphthene), nephropathy (250 mg/kg/day of fluoranthene or 125 mg/kg/day of pyrene) and hematological effects (250 mg/kg/day of fluorene). No effects were reported following doses of up to 1,000 mg/kg/day of anthracene (USEPA 1989b, 1989c, 1989d, 1989e, 1988). The oral RfD values derived for these PAHs are listed below, along with their corresponding NOAEL/LOAEL values, uncertainty factors, confidence and references. An uncertainty factor of 3,000 was used to account for inter- and intraspecies variability, less-than-lifetime exposure and the lack of toxicity data in a second species. Confidence in these values was rated low.

Chemical	NOAEL, mg/kg-day	UF	RfD, mg/kg-day	Confidence	Study
Naphthalene	35.7	10,000	4E-3	--	NTP 1980
Acenaphthene	175	3,000	6E-2	low	EPA 1989
Anthracene	1,000	3,000	3E-1	low	EPA 1989
Fluoranthene	125	3,000	4E-2	low	EPA 1988
Fluorene	125	3,000	4E-2	low	EPA 1989
Pyrene	75	3,000	3E-2	low	EPA 1989

In order to estimate noncancer risks from other PAHs, it is necessary to extrapolate from the values above. On the basis of structural similarities, the RfD for acenaphthene can be applied to acenaphthylene, the RfD for naphthalene can be applied to 2-methylnaphthalene, and the RfD for pyrene can be applied to all PAHs which contain 3 or more rings, for which toxicity information is lacking.

11.2 Carcinogenic Effects

There is substantial evidence from animal and human studies that many PAHs are carcinogenic. Human data are derived mainly from studies of workers exposed to coke-oven emissions, tars, soots and oils, which contain a mixture of PAHs. The main exposure route in these workers is inhalation, and the main effect is increased incidence of lung cancer (Mazumdar et al. 1975, Redmond et al. 1976). This is supported by several studies in animals, where an increased incidence of respiratory tract tumors occurred following chronic inhalation exposure to benzo(a)pyrene or mixtures of PAHs (Thyssen et al. 1981, Dahl et al. 1985).

Cancer has not been reported in humans following oral exposure to PAHs, but a number of studies in animals indicate that ingestion of benzo(a)pyrene or other PAHs can lead to tumors of the stomach (Neal and Ridgon 1967, Snell and Stewart 1962). There are also a number of animal studies which demonstrate repeated dermal contact with benzo(a)pyrene or other PAHs leads to increased incidence of skin tumors (ATSDR 1987, 1990b).

Based on these studies, it appears that the greatest risk of carcinogenic effect from PAHs is at the point of contact, i.e., lung cancer following inhalation exposure, stomach cancer following oral exposure and skin cancer following dermal exposure. This is probably because the PAHs are readily metabolized at the point of contact and that metabolic intermediates are responsible for the carcinogenic response (ATSDR 1990a).

It is important to stress that not all PAHs have been found to be carcinogenic. The PAHs which have been ranked as probable human carcinogens (Group B2) by the USEPA include:

Benzo(a)anthracene
Benzo(b)fluoranthene
Benzo(k)fluoranthene
Benzo(a)pyrene
Dibenz(a,h)anthracene
Indeno(1,2,3-cd)pyrene
Chrysene

All other PAHs have been ranked as Group D (not classifiable as to human carcinogenicity) or have not yet been classified. However, it should be noted that certain aminated or nitrosylated derivatives of some of the noncarcinogenic PAHs are carcinogenic (e.g., 2-aminofluorene, 2-naphthylamine, 1-nitropyrene).

Data are too limited to permit quantitative evaluation of cancer risk for any of the PAHs except benzo(a)pyrene. For benzo(a)pyrene, the USEPA proposed cancer slope factors of 1.15E+01 $(mg/kg\text{-}day)^{-1}$ and 6.1E+00 $(mg/kg\text{-}day)^{-1}$ for the oral and inhalation routes, respectively (USEPA 1991), based on a chronic benzo(a)pyrene feeding study in rats (Neal and Rigdon 1967) and a chronic benzo(a)pyrene inhalation study in hamsters (Thyssen et al. 1981). These values are not yet verified and are currently undergoing review by a USEPA workgroup (USEPA 1991).

In general, there are two approaches by which cancer risk can be estimated for carcinogenic PAHs which lack slope factors. The most conservative approach (which was used in this risk assessment) is simply to assume that all such PAHs are as potent as benzo(a)pyrene. An alternative approach is to assign a relative potency factor (RPF) to each carcinogenic PAH, based on *in vivo* and *in vitro* structure-activity relationship studies (Chu and Chen 1983, USEPA 1989f). By the second approach, benzo(a)fluoranthene and dibenzo(a,h)anthracene are judged to be as potent as benzo(a)pyrene (RPF=1). Benzo(a)anthracene, benzo(k)fluoranthene, indeno(1,2,3-cd)pyrene and chrysene were all determined to be about 1% as potent as benzo(a)pyrene (RPF = 0.01).

12.0 VANADIUM

12.1 Noncarcinogenic Effects

Most reported cases of acute vanadium toxicity resulted from inhalation of vanadium fumes, with effects that are apparently limited to the irritative actions on the respiratory epithelium. This effect has been observed in humans exposed to concentrations of approximately 0.1 mg/m^3, but were not noted at concentrations of 0.06 mg/m^3 (ATSDR 1990). In most of these cases, exposure is not solely due to vanadium, and hence, the effects cannot be clearly attributed to vanadium. In the case of Zenz et al. (1962), however, workers developed adverse effects within 24 hours of initial exposure as a result of processing (pelletizing) purified vanadium pentoxide. The clinical picture consisted of burning eyes, sore throat, dry cough and wheezing rales. Rales lasted three to seven days, and cough persisted for up to two weeks. No effects were recorded which were not clearly associated with irritation of the respiratory or conjunctival epithelium. Williams (1952) described similar respiratory complaints in eight men exposed to vanadium dusts while cleaning oil-fixed boilers. Additional symptoms included listlessness, pallor and "low spirits."

"Green-tongue" is an apparent effect due to vanadium exposure (Williams 1952, Vintinner et al. 1955). Musk and Tees (1982) reported the occurrence of asthma, respiratory symptoms and green discoloration of the tongue in four men working in a vanadium pentoxide refinery. The two men with most recent exposures also displayed bronchial hyperactivity to histamine. The authors concluded from their findings that vanadium may be an asthmogen. In animals, the lungs appear to be the primary target for inhaled vanadium. At the respective concentrations of 2.5 and 4.7 mg/m^3, monkeys displayed an increased pulmonary resistance and rats developed alveolar proteinosis (ATSDR 1990).

Data on actual exposure levels leading to these effects in humans are inadequate and no inhalation RfDs have been determined by USEPA (USEPA 1992).

Studies employing clinical administration of vanadium to produce lower cholesterol levels also provide data on adverse effects. Oral administration of vanadium (diammonium vanado-tartrate) has been shown to cause gastro-intestinal effects at doses of 75 to 125 mg/day in humans (Somerville and Davies 1962, Dimond et al. 1963). At a dose of 50 mg/day or more, a purple-green tint on the tongue was observed by Dimond et al. (1963). Curran et al. (1959) observed no signs of vanadium toxicity when it was administered to healthy males at 100 to 125 mg/day. Comparison of the results of Curran (1959) with those of Somerville and Davies (1962), whose patients had ischemic heart disease, xanthomatosis tendinosum or hypercholesterolemia at the start of the treatment, suggests that humans who are ill may be more sensitive to vanadium than healthy people.

Several animal studies indicate vanadium is acutely toxic (Ballotta 1931). In rabbits, a dose of 1.1 mg/kg-day administered by gavage for one month was harmless, but higher doses (up to 5.5 mg/kg/day) exerted adverse effects on the vasomotor and respiratory centers of the nervous system, accompanied by

hyperemia in the encephalon, lungs, kidney and intestine. In rats, Franke and Moxon (1937) reported reduced weight gains and diarrhea when 2.0 mg/kg/day $NaVO_3$ was administered in the diet for 100 days. No effects were noted by Stokinger et al. (1953) in rats consuming 0.89 mg/kg/day vanadium pentaoxide. Schroeder and Balassa (1967) found that a daily dose of 0.50 mg/kg/day $VOSO_4$ for a lifetime produced no toxicity in mice. No effects were noted by Stokinger et al. (1953) in rats consuming 0.89 mg/kg/day vanadium pentoxide. Schroeder et al. (1970) showed that a daily dose of 0.7 mg/kg/day vanadium (2.24 mg/kg/day vanadyl sulfate) produced no toxic effects in rats after lifetime exposure. The USEPA has derived oral RfDs of 7E-3, 2E-2 and 9E-3 mg/kg/day, based on the NOAEL values of 0.7, 2.24 and 0.9 mg/kg/day (Schroeder et al. 1979; Stokinger et al. 1953) for vanadium, vanadium sulfate and vanadium pentoxide, respectively (USEPA 1991, 1992). The NOAELs were divided by an uncertainty factor of 100 to account for inter- and intraspecies variability. The RfD for vanadium pentoxide has been verified by a USEPA workgroup, and the verification of the other two is currently listed as pending. Confidence in the vanadium pentoxide RfD is rated low due to a lack of information in the critical study and a lack of supporting data (USEPA 1992).

12.2 Carcinogenic Effects

No information on the carcinogenicity of vanadium was located. Three animal studies, however, concluded that vanadium was not carcinogenic. Schroeder and Balassa (1967) administered vanadium to mice in drinking water (5 ppm) from weaning to natural death. Significantly fewer spontaneous tumors were observed. Schroeder et al. (1970) repeated the experiment with rats obtaining similar results. Stoner et al. (1976) investigated the induction of lung adenomas in mice with repeated injections of vanadium over a three-week period (dose level up to 120 mg/kg/mouse). The results were negative.

The USEPA has not assigned a weight-of-evidence classification to vanadium.

12.3 Beneficial Effects

Vanadium deficiencies have been produced in two or more animal species (FNB 1989). Deficiency symptoms included decrease in perinatal survival, growth, hematocrit, plasma cholestrol and lipids, and phospholipids in the liver (Shils and Young 1988). This suggests that there may be essential functions for vanadium in animals, and perhaps in humans. On the basis of available information, however, a human requirement cannot be defined (NAS 1989).
