Re: Docket ID No. EPA-HQ-OW-2016-0438, Request for Public Comments To Be Sent to EPA on Peer Review Materials To Inform the Safe Drinking Water Act Decision Making on Perchlorate

Dear Mr. Hernandez:

The Association of Metropolitan Agencies (AMWA) is an organization representing the largest publically owned drinking water utilities in the United States. Any changes in the development of national primary drinking water regulations significantly impact our members. EPA has published a request for comment on the draft report: *Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water.* AMWA has been involved with the issue of perchlorate since EPA first began pursuing a regulatory determination.

AMWA appreciates the work that EPA has done in order to make a scientifically sound decision on the regulation of perchlorate. The multiple reviews and drafts that EPA has compiled in order to develop a reliable and precise model for determining the impact of perchlorate is a valuable scientific approach. While AMWA agrees that there is a possible correlation between perchlorate exposure and iodine uptake, which in turn may impact thyroid hormone levels, the association has concerns with the methodology of the model and its use to extrapolate possible neurological outcomes in children. AMWA is not certain that the model is precise and reliable enough to determine a thyroid hormone level that corresponds/correlates with perchlorate exposure and is concerned with the possible biases that are introduced by using the model's output with already existing neurodevelopment data from the literature in order to make conclusions on the impact of perchlorate on neurodevelopment. Due to the reasons stated above, AMWA is concerned that the methods shown in this report set a worrying precedent for regulatory determination decisions to

AMWA's Comments to EPA on Peer Review Materials To Inform the Safe Drinking Water Act Decision Making on Perchlorate

General Comments

1. The peer review panel in January 2017 advised EPA to include first trimester, but not to exclude the other life stages. EPA focused on only the first trimester for their revised model due to the lack of data for other stages and the stronger relationship between hormone levels and neurodevelopmental outcomes in early pregnancy. However, the original model encompassed late trimester and infancy, particularly in regards to bottle and breast-feeding infants. EPA states that excluding these stages allows for a simplified model. AMWA requests that EPA give more explanation as to why the model was limited to the first trimester instead of just expanding the original model in order to evaluate all stages. AMWA also suggests that EPA discuss the biases and uncertainties that are added to EPA's analysis by only looking at this life stage.
2. Although this has been stated in previous discussions, AMWA reiterates that a lack of iodine may be the larger factor contributing to thyroid dysfunction regardless of perchlorate exposure. According to the report, one six month study found no changes to thyroid function, but the subjects had higher than average concentrations of iodine, which the report suggests may have been protective. AMWA recommends EPA discuss the possibilities for why no change in thyroid function was found and if iodine deficiency may be the larger factor in thyroid dysfunction.
3. A second statement in the report (p. 3-13) mentions that "there is little predicted change in the percentage drop in fT4 or percentage increase in TSH between gestational weeks due to perchlorate exposure, although baseline TSH and total T4 levels do vary significantly with gestation. However, there is a significant drop in fT4 and increase in TSH with decreased iodide intake in the absence of perchlorate exposure. AMWA recommends that EPA discuss possibilities for why there is little change in fT4 due to perchlorate exposure and if the major factor again might be iodine intake.
4. According to Huber et al. (2011), drinking water contributes 20% to perchlorate intake and food contributes 80%. For the studies cited, is food intake accounted for and if so, how much effect from perchlorate is due to solely drinking water?
5. In section 8, the report lists many other possible health concerns regarding perchlorate. In particular, in section 8.3 (p. 8-2) it is stated that the Comparative Toxicogenomics Database (CTD) "identified 455 diseases potentially associated with perchlorate." However, in the paragraph below (p. 8-3) this statement it is said "connecting perchlorate with other adverse outcomes such as neurodegenerative diseases is highly uncertain at this time. Until more detailed information is collected that will allow the CTD to be used for hazard assessments, it is currently limited to hypothesizing adverse outcome pathways and designing additional studies to more completely understand the range of

ED_005043_00062727-00041

adverse health effects associated with perchlorate." What is the reasoning for including these statements linking perchlorate to a variety of conditions if it is limited to only hypothesizing?

6. There seems to be a variety of studies that conclude perchlorate does affect TSH and fT4 levels, particularly the studies used in this report, but there are also many studies that have found no correlation. For example, Pearce et al. (2010, p. 3321) found that there was "no association between urinary perchlorate levels and first-trimester serum TSH or FT_4 levels." A second study by Brent (2014, p. 4066) stated, "Perchlorate was detected in the urine of all women studied, but there was no correlation of perchlorate levels in the urine with maternal thyroid function. This finding was especially significant because the median iodine intake in Cardiff and Turin, 98 and 52 μg/L, respectively, was relatively low. Individuals with lower iodine intake are thought to be more susceptible to the negative effects of perchlorate exposure." In one of the more recent perchlorate studies (Leung, Pearce and Braverman 2014, p. 376), the conclusion was as follows; "Available data thus far have been inconsistent in demonstrating a correlation between low-level perchlorate exposure and thyroid dysfunction, particularly among those most vulnerable to even mild thyroid dysfunction. Ongoing research is needed to help better understand the potentially adverse effects of human perchlorate exposure, especially in light of recent discussion to proceed with costly longterm perchlorate regulation in U.S. drinking water."

   What reasoning does EPA have for the variation in findings from these studies? AMWA recommends that EPA discuss if there is sufficient data to determine a relationship between perchlorate and hormone levels during pregnancy, particularly at lower levels within sensitive populations.

Precision and Reliability of the Model

1. In section 3.5, it is stated that the incorporation of a feedback loop in the model introduces uncertainties. Fitzgerald and Bean (2016) are cited within the report stating that increasing TSH levels do not have a consistently predictable impact on T4 levels. The report goes on to cite Hadlow et al (2013), which indicates the relationship between TSH and T4 levels is consistently a decreasing function but that it is variable with many factors. AMWA recommends that EPA discuss how the uncertainty of this relationship impacts the reliability and precision on the model.

2. A significant portion of this report relies on the correlation between low thyroid hormone in the first trimester of pregnancy and decreased neurodevelopment. There are recent studies that have shown a high concentration of thyroid hormone may have similar detrimental effects on neurodevelopment, including one of the five case studies used for this report, Korevaar et al. (2016). AMWA recommends that EPA discuss how certain and reliable the correlation is between thyroid hormone in pregnancy and its impacts on neurodevelopment.

ED_005043_00062727-00042

3. In section 3.3.1, the report indicates that NHANES 2007-2012 data for non-pregnant women was used as part of a parameter calibration procedure to simulate population percentiles of fT4, T4, T3, and TSH due to limited data in the range of iodine intake levels of below 75 μg/day. With limited data below 75 μg/day and no data for pregnant women, AMWA recommends that EPA discuss the reliability of this data for use as a calibration for a parameter within the model.

Isolating Perchlorate as the Main Contributing Factor

1. In section 3.5 it is stated that clinical toxicology and occupational studies in high dose subjects showed minimal changes in hormone levels. These populations are not sensitive, nor are they the life stage that the model attempts to study, however, how does EPA explain the lack of a hormonal response at even high doses?
2. This report states that iron deficiency may also cause hypothyroxinemia. A study by Yu et al. (2015) found an association between iron deficiency and isolated hypothyroxinemia in both pregnant and non-pregnant childbearing-aged women, independent of the effects of iodine. A second study (Chang et al. 2013) found a possible correlation between iron deficiency and psychomotor development index (PDI), a factor that two of the studies in this report use to determine the effects of perchlorate exposure. The U.S. Preventative Services Task Force stated in a 2015 report (Siu 2015) that there is little data for the percentage of individuals in the U.S. with iron deficiency. With this in mind, how do you isolate the impacts of perchlorate and account for the possibility of iron deficiency?
3. Figure 5 in section 3.4 (p. 3-13), states the figure "shows that the BBDR model predicts very little difference in non-pregnant and first- trimester response to perchlorate. This likely occurs because the half-life of (organified) iodine in the adult thyroid is around six months, hence the availability of thyroidal iodine in the first trimester pregnant woman is determined to a very large extent by her nutrition and perchlorate exposure several years preceding pregnancy." How does this model account for the possibility that perchlorate exposure's impact on iodine uptake is determined by the years leading up to pregnancy? If considering perchlorate impacts years before pregnancy, how would you exclude other possible factors? AMWA recommends that EPA discuss how these uncertainties impact the reliability and output of the model.

Uncertainties within the Model and Study

1. In section 1.1.2, the report states that the adult thyroid contains several months of T4 stored in the colloid and that it is not expected to see a result in thyroid status in only a two-week study. The five studies selected only looked at thyroid hormone levels at certain points during pregnancy. Some only used hormone values taken at one point during gestation. AMWA recommends that EPA discuss how much uncertainty this brings to the model's output.
2. The report states that the relationship between fT4 and neurodevelopment is still very much evolving. AMWA recommends that the panel discuss the reliability

and certainty of fT4 level impacts on neurodevelopment. AMWA also recommends that EPA discuss any variations in recent findings related to the relationship between fT4 levels and neurodevelopment.

3. Of the five studies used with the model, only two assessed iodine status. With the large impact that iodine has on thyroid hormone levels, AMWA recommends that EPA discuss how much uncertainty this lack of data brings into the results of the report.

4. The populations from the studies used with the model are not from the US, but instead are from the Netherlands and Italy. The report says there is no reason to believe that the impact of fT4 would vary by country unless there is a substantial difference in iodine intake and that three studies showed that iodine intake was similar between the Netherlands and the US. How sure is EPA of this statement, in particular in light of the case studies reviewed, as only two gave data on iodine status? Does EPA have more data to support this postulate?

   Are there other environmental factors that could be influenced based on geographic location? In particular, how does the Vermiglio (2004) study, one of the five studies used, which is in northern Sicily, compare to iodine levels in the U.S.? Two studies (Andersson, Karumbunathan, & Zimmermann 2012; Lazarus 2014) looked at trends in iodine deficiency and found that Europe tended to be iodine deficient, accounting for over a third of the iodine deficient countries in the world, and that the U.S. was, as a whole, iodine sufficient. Zimmermann's 2012 study specifically stated that Italy was iodine deficient including within the pregnant population. Although this study did mention that the Netherlands, where the other four studies have occurred, had levels of iodine within pregnant women that was deemed sufficient.

   AMWA recommends that EPA discuss the possible uncertainties and bias that this assumption brings into the study.

5. The model was limited to using fT4 levels at 12-16 weeks gestation based on a recommendation from the Science Advisory Board (SAB) during the initial review of the model. In section 2.6, the report states that fT4 levels aren't as impactful after 16 weeks, but are still involved in some measure. AMWA recommends that EPA discuss in more detail how much impact fT4 levels can have past 16 weeks gestation and how this might impact the results of the study in relation to neurodevelopment.

6. In section 6.5.2 (p. 6-16) it is stated that "it is difficult to ascertain the true implications of a change in the standard deviation of reaction time, the endpoint with which there is a significant association with maternal fT4 levels." If the implications are so uncertain, why use this study? AMWA recommends that EPA discuss how this uncertainty may impact the interpretation of the results of the report.

7. In section 6.5.5 (p. 6-18) it is mentioned that thyroid tests have yet to be standardized, but that this shouldn't pose a problem "because all individuals in the papers were assessed using the same techniques, any bias resulting from this

source of uncertainty would likely be random and would tend to bias toward the null." This appears to suggest that the same tests are used within each single study, but not necessarily throughout all five chosen studies. AMWA recommends that EPA explain why using different tests among studies wouldn't bring any uncertainty to the results.

8. One study that is referenced for showing significantly increased adverse health affects, particularly in regards to IQ (Taylor et al. 2014, p. 4296) explicitly states in the paper that their "results should be interpreted with caution and analysis viewed in the context of hypothesis generation, although the observed deleterious effects principally on VIQ are in keeping with a recent study of maternal iodine deficiency and subsequent offspring cognitive development. We would not recommend action on perchlorate levels from this study alone, although our report highlights a pressing need for larger studies of perchlorate levels from the general pregnant population and those with undetected hypothyroidism. Future studies should utilize samples taken at several stages of pregnancy with subsequent neonatal thyroid function and more detailed cognitive development of offspring, in particular VIQ." VIQ meaning verbal IQ.

   In light of the author's recommendation, AMWA recommends that EPA discuss whether or not the science has come far enough since this study to make a conclusive determination that perchlorate has an effect on IQ in offspring, particularly since hormone levels are only being considered during weeks 12-16 of gestation.

9. Three of the studies (Pop et al. 1999; Pop et al. 2003; Vermiglio et al. 2004) all had very small sample sizes at 22, 57, and 27 individual children respectively. In comparison, the other two studies used significantly larger sample sizes at 3,839 and 1,765. AMWA recommends that EPA discuss the reliability of the conclusions for the three smaller studies.

Possible Bias

1. In section 5.1, the literature review procedure is discussed. It is mentioned that "search strings" were used in order to find studies that may work best within the model EPA has created (i.e. neurodevelopment AND hypothyroxinemia; hypothyroxinemia AND autism; etc.). AMWA recommends that EPA discuss the biases, if any, that this method brings into determining the effect of hypothyroxinemia on neurodevelopment.
2. The procedure utilized to determine which studies were to be used were only ones that found significance between fT4 and neurodevelopment, the reasoning for this being that only these studies would work within the model. In section 6.5 (p. 6-14) the report states, "one global uncertainty in this analysis is that the state of the science on the relationship between maternal fT4 levels and offspring neurodevelopment is constantly evolving." AMWA recommends that EPA discuss the biases introduced into this report by only using these five studies and the method utilized to select them.

ED_005043_00062727-00045

3. Hypothyroxinemia is defined in the report (p. 2-4) by the Science Advisory Board's definition of "a variety of cutoffs….ranging from fT4 below the 10th or 5th percentiles to below the 2.5^{th} percentile." This report used the 10th percentile. According to Dosiou and Medici (2017, p. R24), "there are substantial differences in the definition of IMH between studies, which significantly affect the interpretation of prevalence data for this condition." Why was the 10th percentile chosen? When looking at the "shift" of women who become hypothyroxinemic due to perchlorate, how might these numbers be different if using the 2.5^{th} percentile? AMWA recommends that EPA discuss the biases, if any, this may bring to the report.
4. Different neurodevelopment measurements are used with the model; two studies look at PDI, two look at IQ, and one looks at reaction time. As a whole there are five studies, but in actuality there are three different unknowns between them. This inherently leaves smaller sample sizes for each parameter and, as discussed above, some of these data sets are already quite small. With the amount of data on each single factor, AMWA recommends that EPA discuss whether or not there is enough data to support the findings and if more studies should be analyzed before drawing a conclusion.

Re: Comments on the Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water (82 FR 43354, EPA–HQ–OW–2016–0438)

Dear Sir or Madam:

The Chlorine Institute ("CI" or the "Institute") is a 190 member, not-for-profit trade association of chlor-alkali producers worldwide, as well as packagers, distributors, users, and suppliers. The Institute's mission chemicals, namely chlorine, sodium and potassium hydroxides, sodium hypochlorite, the distribution of vinyl chloride monomer (VCM), and the distribution and use of hydrogen chloride, are used throughout the U.S. economy and are paramount to the protection of public health.

The Chlorine Institute would like to submit the following comments to the United States Environmental Protection Agency's (EPA's) recent request for public comment on the "Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water'' (draft MCLG Approaches Report) Volumes I, II, and III as noted in the September 15, 2017, Federal Register notice (FRN, 2017).

Epidemiology Data Used in the Model: The data used to establish parameters for the model, calibrate the model, and validate the model relies heavily on epidemiology data in early pregnancy. While we agree that an extension of the model to include early pregnancy would be

ED_005043_00062727-00050

beneficial to capture a vulnerable time of brain development and the impact of perchlorate on thyroid hormones, the quality of the available data should be highly considered and evaluated. Epidemiology, focused on human populations, is heavily biased with confounding factors that can impact the effects of perchlorate on thyroid hormone levels, as noted throughout the current draft document. Confounding factors that are difficult to control in human epidemiology studies include identification of smokers, diet, previous disease status, dietary supplement intake etc., all of which can impact levels of thyroid hormones and perchlorate exposure. EPA does not provide justification for excluding pertinent animal studies such as that by Mahle et al., (2003) in which pregnant rats were administered perchlorate in drinking water from gestation day 2 and thyroid hormone levels were measured. Animal studies may provide useful data that have been conducted in well controlled environments with less genetic variability. In fact, Clewell et. al., (2003) developed and published a PBPK model in rat modeling fetal perchlorate dose and inhibition of iodide kinetics during gestation.

Literature Review - Group 1 Study Selection. It is unclear why EPA chose to not include studies with results that were not statistically significant in the association between fT4 and neurodevelopment outcome. These studies would add value in determining hormone levels during pregnancy and neurodevelopment outcome (Ghassabian et.al., 2014; Modesto et.al., 2015; Moleti et. al., 2016; Noten et.al., 2015; Oken et.al., 2009; Velasco et. al., 2009) EPA's reason, for example, for not including the data form the Noten et. al. (2015) paper states that "statistical significance was lost after controlling for confounders" (EPA, 2017, Section 6.0, Table 22). Without taking into consideration studies in which no neurodevelopmental effects were found, creates a bias within the model and therefore the model lacks robustness in informing derivation of an MCLG.

Failure to address other goitrogens in the model. The lack of consideration of other goitrogens such as thiocyanate, which has been shown to compete with perchlorate to inhibit NIS and also is a competitive substrate for thyroid peroxidase, the enzyme required to form T3 and T4 from thyroglobulin and iodine (Steinmaus et al., 2007; 2013), can lead to uncertainty in the model results. It is not enough to justify the lack of consideration and effect of other goitrogens by saying that the model simulates mothers with low iodine intake and low baseline fT4 which addresses the sensitivity to high exposure of other goitrogens (EPA, 2017, Section 3.5, page 3-

ED_005043_00062727-00051

15). Additional data should be considered in the model of how other goitrogens can alter availability of thyroid hormones as well as iodide's interaction with the NIS.

Further, the model assumes that exposures to perchlorate and other goitrogens vary independently in the population and that the effects are additive (EPA, 2017, Section 3-5, p.3.17). The assumption that the effects are "additive" should be further evaluated and clarified. As noted above, other goitrogens can have additional effects on the thyroid hormones that are not consistent with the perchlorate mode of action. Making the wrong assumption on this point can greatly impact the predictions of the effects of perchlorate on neurodevelopment.

Therefore, EPA cannot ignore the effects of other goitrogens on the transport of iodine into the thyroid. Pursuant to Section 1412(b)(4) of the Safe Drinking Water Act (SDWA), the Maximum Contaminant Level Goal (MCLG) "shall be set at the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." In order to meet this obligation, all goitrogens should be considered in the PBPK model rather than focusing solely on one goitrogen.

Variable expression of the NIS gene. As EPA states, "The degree to which there is inter-individual variation in NIS structure and/or regulation contributing to variance across the population in the impact of perchlorate exposure on thyroid function is currently unknown" (EPA, 2017, Section 3.5, p. 3.16). As supporting data that variation in the NIS gene exisits, EPA sites a paper by Al-Rasheed et al. (2015) who identified variations in the NIS gene that could lead to development of differentiated thyroid cancer. This data indicates that variability in the expression of the NIS gene could render some individuals more or less sensitive to exposure to all goitrogens. This variability, while it has been recognized as an uncertainty within the model, should be considered within the parameters of the mode.

Limited data on toxicokinetics and toxicodynamics of perchlorate. EPA does acknowledge there is limited data on the effects of perchlorate on circulating hormone levels needed for the model (EPA, 2017, Section 3.5, p.3-16). It is noted that clinical toxicology and occupational studies show minimal changes in the thyroid hormone levels (Braverman, et. al., 2007). Epidemiology studies with low exposures, however, show associations between urinary

ED_005043_00062727-00052

perchlorate, increases in TSH and decrease in T4 (fT4) (Blout et al., 2006, Braverman et. al., 2007, Steinmaus et. al., 2016). The lack of toxicodynamic and toxicokinetic data, especially during pregnancy, could impact the prediction of fT4 on neurodevelopmental outcomes. This puts the validity of the model at question. Additional studies should be conducted to increase the validity of the model if using the model to influence and set regulatory standards.

Incorporation of the TSH feedback loop. TSH levels do not have a consistently predictable impact on T4 levels according to Fitzgerald et. al., (2016), due to interindividual variations including genetics, subclinical thyroid disease, age, and gender. The model does account for some of the variability and does make an association between weak responders and strong responders however, not within a fixed set-point. It is important to point out that the whole HPT feedback loop is tightly controlled and that homeostatic set points will vary among individuals. Within this discussion EPA points out that "any exposure to perchlorate is predicted to reduce fT4" (EPA, 2017, Section 3.4, p.3-17). However, a no observed adverse effect level (NOAEL) was established in humans at 7 μg/kg/day in which perchlorate inhibition of radioiodine uptake by the thyroid (Greer et. al., 2002) (EPA, 2017, Section 3.4, p. 3-14). In fact, EPA incorrectly cites this level as the NOAEL but Greer et al, 2002, cite this level as the No Observed Effect Level (NOEL), the level at which no statistically or biologically significant increases in the frequency or severity of any effect is observed. This clearly indicates there is a dose at which perchlorate does not impact iodide uptake by the thyroid and therefore fT4. This statement should be changed to reflect the dose-response of perchlorate on fT4 levels. In additional, perchlorate acts on the NIS to alter iodine levels, not directly fT4 levels. The model's only output being considered is the effect of perchlorate on free thyroxine (fT4) and no other measures of thyroid function. To understand the complex feedback and homeostatic mechanisms in the hypothalamic-pituitary-thyroid axis, several measures of thyroid function should be modeled, including, T3, T4, TSH, thyroglobulin, and thyrotropin releasing hormone.

Determining Distribution of fF4. The literature review suggests that gestational weeks 12, 13 and 16 were best to focus on and further that the fT4 is best to assess in order to calibrate the model for the median-iodine intake. However, the data is very limited at these time points during gestation. Specifically, Li et. al., 2014), Männistö et. al., 2011), and Zhang et. al., 2016) were evaluated for weeks 12 and 13. Only Männistö et. al., 2011) and Zhang et. al., 2016) were

ED_005043_00062727-00053

evaluated for week 16. Only one study evaluated week 13 (Männistö et al., 2011). Further it is difficult to determine whether the lognormal distribution can be applied versus a normal distribution with such limited data. Additional data should be considered at additional gestational timepoints in the first trimester (EPA, 2017, Section 4.1, p. 4-1). Perhaps the studies that measured levels of fT4 at various gestational time points in Group 1 of the literature reviewed but were disregards by EPA as not having statistical significance could be helpful here.

Failure to address compensation and adaptation. Critical assumption for concern in the model is that there is no compensation or adaptation of thyroid hormones, levels of iodide, or changes in expression of the NIS considered. As noted already, homeostatic control of the HPT axis, iodide intake and gene expression of NIS are all variable and as such compensatory mechanisms or mechanism of adaptation to varying levels of thyroid hormones, iodide and NIS expression should be included in the model to more accurately reflect the effects of perchlorate on neurodevelopmental outcomes.

Neurodevelopmental endpoint selection. It is unclear why EPA selected ADHD and autism in their literature search as neurodevelopmental endpoints to assess the effects of iodine on thyroid hormone levels (EPA, 2017, Section 5, page 5-1). These are not appropriate endpoints given the spectrum of both diseases. The literature review should focus on studies in which measurable and clearly defined endpoints in the study are reflective of neurodevelopment outcomes.

In addition, neurodevelopment can be affected by many different types of exposure scenarios. A single measurement of thyroid hormone in the first trimester of pregnancy cannot predict neurodevelopment in offspring at one year after birth and up to 10 years after birth. During this period, there are many factors that could affect brain development.

Alternative Approach (Section 7.0). EPA cites that an "alternative option to inform future decisions on the derivation of an MCLG using the BBDR model is to evaluate a shift in the proportion of the population that will fall below a hypothyroxinemic cut point, given exposure to perchlorate" (EPA, 2017, Section 7, page 7-1). However, EPA indicates this approach does not directly connect the BBDR output to neurodevelopment. It appears the approach is to be preventative in that the shift could prevent an increase in "risk" to the neurodevelopmental impacts of low thyroid hormone levels based on EPA's literature review of hypothyroxinemia

ED_005043_00062727-00054

and adverse neurodevelopmental outcomes. However, the data used in the model should link to neurodevelopmental outcome; otherwise the model will not meet the goal of assessing the effects of perchlorate on neurodevelopment.

In addition, it seems that this approach would increase uncertainty in individual fT4 measurements within a presumed smaller population size. A single fT4 measurement may represent hypothyroxinemia for one individual at a certain time point, but not for the same individual at a different time point or for another individual (EPA, 2017, Section 7.0, page 7-5). There is an assumption that neurodevelopment deficits would occur however, the data does not measure neurodevelopmental outcomes. Again, without the proper data being input into the model, the validity of the model is questionable, rendering the model not useful.

Appendix C: Comparison of the BBDR model with the Steinmaus et al. Data - Change in IQ: In Appendix C of Volume III, EPA makes a comparison between the Steinmaus et. al., (2016) data of urinary perchlorate and fT4 levels in women in urine at 7 weeks of gestation and in blood at 15-20 weeks of gestation to the results of the BBDR model and states that the results of the model indicate it would take 2.91 µg/kg/day to cause a 1 point change in IQ. However, the results of the Steinmaus et. al., (2016) study are only based on one collection time point for each pregnant woman and it appears to be a big assumption that 1 point change in IQ can be determined by one time point in one study.

Independent Review Recommended Prior to Completion. As the model nears completion, it is essential that an independent, third party evaluation and validation of the model be conducted to understand the completed models' strengths, weaknesses and what further improvements may be required of the model before using the model to inform a MLCG for perchlorate.

In conclusion, EPA has made great strides in improving the draft PBPK model to inform a MCLG for perchlorate. However, there are still many limitations of the draft PBPK model that need to be addressed, including the lack of data to calibrate and validate the model specific to sensitive life-stages. We encourage EPA to select peer reviewers with the expertise to evaluate all facets of this model with the understanding that it will be used to inform MCLG which, in turn, will influence global regulatory standards.

Comment

Please see attached comments provided by the US Department of Defense.

Our comments submitted by the Office of the Deputy Assistant Secretary of Defense, Environment, Safety and Occupational Health focus on concerns associated with the lack of systematic review of the literature to support linking clinical data ofdevelopmental effects and low T4 thyroid hormone and the lack of a description of how negative studies were or were not considered in the literature search. We also provide comment and highlight our concern with the additional approach included in the report which is not
based upon developmental effects but rather a population shift towards hypothyroxinemia given exposure to perchlorate. The rationale for inclusion was not described and there are particular technical aspects of it
are troubling, such as a change in perchlorate baseline from the original study whose effect is a significant change in hormone levels, beyond that seen in the original (Steinmaus).

We appreciate the opportunity to provide comment on the technical report and look to EPA to ensure that the peer review panel charge questions address these and any other remaining technical issues with the report.

Department of Defense Comments on
Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water

Comments submitted by: OASD(EI&E), ESOH	Organization: Department of Defense	Date Submitted: 11/17/2017

*Comment categories: Science or methods (S); Editorial, grammar/spelling, clarifications needed (E); or Other (O). Also please indicate if Major i.e. affects the outcome, conclusions or implementation of the assessment.

Comment No.	Section	Pages	Comment	Suggested Action, Revision and References (if necessary)	*Category
1	1.1 Background on Perchlorate	1-1	The text states: "However, the main source of perchlorate currently in the environment is from the production and usage of rocket fuel, by both the defense and aerospace industries (NRC, 2005)." The statement seems outdated, since 2005 several reports have been published that point towards fireworks as contributing to perchlorate in the environment.	Please see and consider Sijimol, MR, "Environmental Impacts of Perchlorate with Special Reference to Fireworks", Environmental Monitoring and Assessment, Nov 2014, vol. 186, pgs 7203-7210.	S
2	2.1 Overview of Thyroid Physiology	2-1	The document states that "T4 is generally thought to act as the prohormone for the more biologically active T3... However, it should be noted that the regulatory factors that modulate the delivery of T4 to the fetus are not fully understood." As EPA is using T4, and not the active T3 in its BBDR model, it is not clear how free T4 can be accurately estimated without this knowledge.	If T3 is the entity that determines effect on development in the fetus, EPA should clarify why it chose to use fT4 as the metric.	S
3	2.1 Overview of Thyroid Physiology	2-1 & 2-2	As noted in comments on Appendix B, EPA acknowledges that selection of the "set-point"	EPA needs to not only more completely justify its selection of the set-point used, but also, and	S/M

			will significantly affect the results of the model. Here, EPA states "different from individual to individual, which generates a population variance in blood levels of thyroid hormone that is considerably broader than the individual variance ..." Yet the set-point appears arbitrary and definitely does not account for the large variance described in this text.	more importantly, needs to provide information on the effect of using a single value, rather than a range for the set-point, as indicated by the information presented in this paragraph.	
4	2.1 Overview of Thyroid Physiology	2-2	"It is generally thought that" plus citing one partial example does not support the hypothesis.	If it is indeed generally thought, then either a review article or a text book citation should be available and should be cited. If not, suggest that this paragraph be deleted as it would not be sufficiently scientifically supported.	S
5	2.4 Perchlorate's Impact on Thyroid Physiology	2-6	The NIS km for perchlorate is 60% of that originally predicted and the rationale is provided. However, simulations of the improved fits of radioiodide uptake in thyroid are not provided.	To lend some transparency, please provide some simulations of inhibition of radioiodide uptake in the thyroid from Greer et al. (2002) or other studies.	S
6	2.4 Perchlorate's Impact on Thyroid Physiology	2-6	Since EPA states that "PCBs, polybrominated diphenyl ethers (PBDEs), bisphenol A, and perfluorinated acids (PFAs), also disrupt thyroid homeostasis", it is important that the document clearly state if the data used in the PBPK model appropriately accounts for potential exposure to these confounders.	As there is wide-spread and variable exposure to the chemicals named, and as EPA notes that co-exposure, e.g., smoking, can cause synergistic effects, it is important that the data used to estimate dose-response effects be adjusted for these exposures or the variability acknowledged to the extent possible.	S/M
7	2.5 Distribution and Excretion of Perchlorate	2-27	Relying on inferences from recent, apparently not replicated, in vitro studies EPA infers that "if this is the case, additional stimulation by maternal TSH in the presence of perchlorate may result in an absolute increase in NIS and	Since as the document states, "there is no direct evidence to indicate that the quantity of placental NIS is upregulated in response to increased TSH", EPA should qualify the conclusions from its model with this caveat.	S

			subsequently increase perchlorate transfer to the placenta."		
8	3 Overview of EPA's Biologically Based Dose Response Model	3-1 - 3-18	Plasma protein binding may be contributing to fT4 remaining extremely low, while the pituitary is still producing normal TSH levels under hypothyroxiemia. Under normal conditions, 90% of plasma bound iodide is T4 and approximately 5% is T3 (Berkow et al., 1977). Plasma inorganic iodide is about 0.4 +/- 0.23 ug/dl (Elte et al.,1983). Dissocation of free iodide involves both deiodination and dissociation from serum proteins. It appears that a fraction of total iodide and THs were applied to distinquish these concentrations.	Please clarify how plasma protein binding of iodide or thyroid hormones were handled and what limitations the approach has for simulating altered fT4. Describe if a constant percentage was used.	S/M
9	3.1 Background and Structure of BBDR Model Development	3-3	Since Lumen and George have updated their model, it would seem reasonable to (1) note any differences between EPA's changes and those of the authors of the model, and (2) determine if the two versions provide reasonably similar results.	Since two models are available, both should be utilized to at least some degree. This is especially important if any parameters were changed in the 2017 Lumen and George analysis, as "Table 1. Summary of Major Features of Current BBDR Modeling" only discusses parameters from Lumen et al. (2013). This analysis should reflect the current state of the art.	S
10	Background and Structure of BBDR Model Development	Figure 4	Much work has gone into development of this report and in the process, the BDDR model has been simplified in some respects from the previous version and enhanced in others (such as the TSH feedback). The fetus and placenta were lumped with the "rest of body"	Include the fetus and placenta in the model and predict the effect of perchlorate on total fetal iodide. If this has already been done during earlier revisions, please discuss the outcome and why it was abandoned.	S/M

			compartment because their volumes are too small to affect the evaluation of sensitive parameters. However, the fetus is the endpoint. Data are extremely limited for these "tissues", but fetal and placental iodide concentrations were simulated in Clewell et al., 2007 and calibrated aginst data of Aboul-Khair et al. (1966); Dyer et al. (1969); Dyer and Brill (1972). It is true that the small volume of the fetus and placenta will not likely impact on perchlorate or iodide kinetics in the mother, but their inclusion would allow us to evaluate the parameters to which the fetus is most sensitive.		
11	3.3 Overview of Key Model Attributes	3-8 and Table 1 on page 3-7, first box	hCG may play a much larger role in T4 production than is mentioned here.	Please provide more information about its potential involvement with T4 production than one sentence in a Table with a reference.	S
12	3.4 Results of the BBDR Model	3-10	In the footnote, there is an "l" missing from "Lambert-Meserlian et a."	Please correct.	E
13	3.4 Results of the BBDR Model	3-10	Given the recommendations in the footnote on this page, it is difficult to understand why EPA chose to only evaluate fT4 in its modeling. The American Thyroid Association's recommendation to use TSH post-date those of EPA's SAB, and should be considered to have some authority.	Since the BBDR model must have also calculated the TSH concentrations for all of the runs that produced fT4 concentrations, we strongly recommend that these data be provided to the public. Even if EPA does not choose to use these data, based on the recommendations of the ATA, other stakeholders may wish to use those data to analyze the effects of perchlorate.	S/M

14	Figure 5 Example Output from the BBDR Modela	3-11	For fT4, there should be an explanation as to why, when the median and lower bound change so much, that the upper bound changes only a little and only at the highest doses. For TSH, we note that only the lower bound changes significantly. The lack of change in the upper bound, and for TSH in the median, suggests that conditions were selected that are sub-optimal for determining the range of iodine status that might be affected by exposure to perchlorate.	Suggest that more data points would improve the knowledge for the decision-maker.	S/M
15	Figure 5. Example Output from the BBDR Modela	3-11	As currently formatted, the key for the 4 graphs in this figure blocks some of the data.	Please move the key.	E
16	3.4 Results of the BBDR	Tables 2 and 3	Both tables require checking and review in order to provide accuracy, clarity, and transparency.	Each issue will be addressed in a separate comment.	S/M
17	3.4 Results of the BBDR	Table 2	Although this comment may be due to rounding errors, we note that, with the exception of the final value, the penultimate column has exactly the same (to 3 figures) concentration of TSH, but the percentage change ranges from 0.04 to 0.21.	If the data can support more than 3 significant figures, they should be provided. If the data cannot support 4 or more significant figures, then the percentage change is scientifically meaningless and should not be presented.	S
18	3.4 Results of the BBDR Model	Table 2	It is not possible to check the percentage change in the penultimate column for most of the values, as the data presented do not allow for this calculation. For the highest calculation, however, and assuming the usual definition of percentage change, i.e., [(1.36 - 1.35)/1.35] x 100 = 0.74 not 0.45 as in the table.	All of the calculations in Tables 2 and 3 should be validated to ensure the values are accurate.	S

19	3.4 Results of the BBDR Model	Table 2 and 3	It is unclear if the changes reported in these table represent a change that is biologically or clinically significant, or whether the estimates are within the range of normal women, pregnant or not.	Percentage change from control does not necessarily represent an adverse effect. For clarity and transparency, the document should provide information as to whether these changes are biologically or clinically significant. We assume they are not statistically significant, or that fact would have been reported.	S
20	3.4 Results of the BBDR Model	Tables 2 and 3	The number of significant figures in these tables is not consistent. In Table 2, fT4 is reported to 4 significant figures, while in Table 3, only 3 significant figures are reported. Assuming the data and analyses are the same, the number of significant figures reported should also be the same. As it is, the number of significant figures reported appears to have been selected to demonstrate a change rather than whether the underlying data support that change. The number of significant figures for percentage change in Table 2 range from 1 to 2; in Table 3, from 2 to 4. First, since only 3 significant figures are presented in the data for Table 3, any further analysis cannot support more than 3 significant figures.	The number of significant figures reported should accurately reflect the precision of the data and the analysis applied thereto. From this presentation, it is unclear if the underlying data support these minimal differences, or if the "changes" may be due to either "noise" in the data or lack of appropriate truncation of the data.	S/M
21	3.4 Results of the BBDR Model	3-13	The substance of the paragraph below Table 3 includes important information and should be included in the Executive Summary.	Since the focus of this analysis is on the first trimester of pregnancy, suggest adding a sentence such as: "During the first trimester, the BDDR model predicts little change in the percentage drop in fT4 or percentage increase in TSH due to perchlorate exposure, although	S/M

				baseline TSH and total T4 levels do vary significantly with gestation".	
22	3.5 Uncertainties Associated with the BBDR Model	3-15	To improve clarity and transparency, it would be useful if there were citations provided to support the following statement: "While the BBDR model does not explicitly consider other goitrogens (e.g., thiocyanate, nitrate), simulating results for a mother with low iodine intake and low baseline fT4 may help to address the sensitivity of individuals with high exposures to other goitrogens."	Since the assumption that perchlorate and other goitrogens are (1) fungible with each other and (2) compete with iodine only based on their Km, it would seem that this statement should be qualitatively and quantitatively supported beyond the assumption.	S
23	3.5 Uncertainties Associated with the BBDR Model	3-17	The following statement is inconsistent with EPA guidance, guidelines, and standard practice that assumes a threshold for non-cancer, adverse effects: "Any exposure to perchlorate is predicted to reduce fT4 to some extent." It is also inconsistent with the statement on page 3-14, "This result is consistent with the underlying Greer et al. (2002) data in human test subjects, which showed a no observed adverse effects level (NOAEL) for perchlorate inhibition of radioiodide uptake by the thyroid NIS of 7 Âµg/kg/day."	Please reconcile and correct.	S
24	3.5 Uncertainties Associated with the BBDR Model	General	The discussion of uncertainties associated with the model is vague in terms of their meaning for protection of public health and is also lacking in terms of quantitative analysis.	Please more clearly discuss whether the uncertainties would tend to underestimate or overestimate threats to the population. If there was a sensitivity analysis performed please describe. In the case of the last paragraph where thyroidtitis is discussed please note	S/M

				whether this was a sensitive subpopulation suggested by the SAB panel or otherwise describe its relevance for purposes of the MCLG determination.	
25	4.1 Evaluation of Distributional Shape and Derivation of the Geometric Standard Deviation		It is neither clear nor transparent why EPA chose to develop a complex model and then not use the model to estimate all of the data in tables 6, 7, and 8. Presumably, the analyses that produced the median that was derived (according to the footnotes) from the model could have also generated the other percentiles of the distribution generated. By only using the median and not the other percentiles, this more complex process (of estimating GSDs from variable data) suggests that there is a problem with the model for all percentiles other than the median.	If the model is only considered accurate for estimating a median, this should be clearly stated and the "problems" with estimating the other percentiles should be discussed. If the model is considered accurate for the other percentiles, those data should be presented. In either case, the "predictions" in these tables based on a weighted, estimated GSD should be compared with the results of the same conditions with the BBDR model.	S/M
26	4.1 Evaluation of Distributional Shape and Derivation of the Geometric Standard Deviation	4-1	This section states that it was a review of the literature that caused EPA to focus on T4 rather than TSH. However, the referenced chapters appear to stress that it was the comments and recommendations of the SAB that cause the switch from TSH to T4. Indeed, EPA's most recent, authoritative reference, i.e., that of the ATA (2017), suggests use of TSH as the metric.	Please clarify, and provide references in this discussion, as to which papers were decisive in EPA's move to T4.	S
27	4.1 Evaluation of Distributional Shape and Derivation of the	4-1	Neither skewness nor that "lognormal function demonstrated a better fit than a normal distribution" are reasons to assume that the distribution is truly lognormal. It would seem	With existing computer power, it is no longer necessary to force distributions to be normal or lognormal. While the analysis is more complex, establishing MCLGs that will lead to regulatory	S/M

	Geometric Standard Deviation		more likely that the distribution is bimodal, i.e., that there is a normal population and a secondary population that is, for whatever reason (genetics, other exposures), low in thyroid. While a bimodal distribution is admittedly more complicated to evaluate, methods exist. For example, random sampling for the BBDR model can be done from a distribution based on data rather than one artificially forced to be lognormal. The method provided in footnote 8 is at best a subjective judgment. Use of Excel for statistical analyses limits the quality. EPA has statisticians with access to statistical software that can perform a more rigorous analysis of these data. This analysis should not be limited by the lack of statistical knowledge of the authors of the document.	MCLs should rely on best statistical practice, not that which is most facile.	
28	4.3 Limitations and Uncertainties of Method	4-6	As the two studies used to select the parameters for the analyses in chapter 4 to this point disagree on the distribution and as the previous comments demonstrate additional limitations of the approach used, it is critical that EPA justify their approach as it appears to be not supportable by the data presented.	If the combined data are neither normal nor lognormal, the distribution should be evaluated based on the empirical data points. If, as suggested here, one data set favors a normal distribution while another favors lognormal, the data should be analyzed both ways to determine if the difference in results is sufficient to continue with both analyses. If these analyses are to form the basis for an MCLG leading to a regulatory MCL, EPA should not arbitrarily select one of two or more options that may lead to quite disparate values for the MCL without a strong, scientific justification that is clearly lacking in this case.	S/M

29	5.2.2 Step 2. Categorize the Remaining Studies	5-3	Since it is unlikely that any study measured maternal hormone levels daily, much less throughout the day, for all of the months of pregnancy, "a continuous measure of maternal thyroid hormone levels" is highly unlikely.	Here and elsewhere, suggest replacing "continuous" with "repeated measures", or otherwise define how “continuous”.	E
30	5.3 Results of Evaluation to Identify Studies That Directly Relate Thyroid Hormone Levels with Neurodevelopment	5-4	The following statement suggests that studies that found that exposure to perchlorate as not associated with neurological effects were ignored in this analysis: "As presented in Figure 6, the literature review identified 55 studies that link thyroid hormone levels to neurodevelopmental effects." Negative as well as positive studies must be examined to provide an unbiased analysis.	Please describe how any studies that did not find an association between perchlorate exposure and neurodevelopmental effects were evaluated.	S/M
31	5.3 Results of Evaluation to Identify Studies That Directly Relate Thyroid Hormone Levels with Neurodevelopment	5-5	Since the BBDR model assumes a quantitative relationship between TSH and fT4, it is not clear why "if the study only had data on TSH" should matter.	Please clarify.	S
32	6 Informing the Derivation of an MCLG: Neurodevelopmental Effects	6-1	It is not clear how the tables of estimated changes in neurodevelopmental outcomes in relation to fT4 and iodine intake are intended to be used by EPA. The first paragraph of the section states "This section demonstrates how EPA could inform the derivation of an MCLG for perchlorate by evaluating how various doses of perchlorate to a pregnant woman may result in	Please describe the intent of the data derived from the analyses and presented in the tables in this section. Please discuss whether they will be combined into a single table or perhaps the outcomes plotted as a function of fT4 and how this may be used to derive the MCLG.	S

			changes in neurodevelopment of her child.", but we see no actual demonstration.		
33	7 Informing the Derivation of an MCLG: Hypothyroxinemia	7-1	The alternative option presented here that uses a shift in the population below the hypothyroxinemic cut point was not suggested by the SAB and is not related to developmental endpoints by EPA in their analysis. It is not clear why it is presented here.	Please clearly describe why this option was deemed necessary for presentation in this document and its purpose for deriving an MCLG.	S/M
34	7 Informing the Derivation of an MCLG: Hypothyroxinemia	7-1	Inclusion of hypothyroxinemia and the alternative option is partially justified by "the preponderance of evidence located in EPA's literature review that finds an association between hypothyroxinemia and adverse neurodevelopmental outcomes." But it is not acknowledged that only a biased search of the literature looking for studies with positive results was performed, there was no systematic review of the literature as is noted in other DoD comments.	Do not use this as a justification to move away from the SAB recommendations unless an unbiased literature search is performed.	S
35	7 Informing the Derivation of an MCLG: Hypothyroxinemia	7-1 - 7-2	This section discusses the results of literature search as if it were nonbiased and would include studies with null results. However, as stated in Section 5.1 a full systematic review was not performed.	Suggest clarifying whether any null results were found and whether the design of the literature search would have precluded them.	S
36	7 Informing the Derivation of an MCLG: Hypothyroxinemia	7-3	The figure and the associated text assume the fT4 versus probability distribution will stay the same during exposure to perchlorate. While this simplifies the analysis, it is highly unlikely. First, the "average" response to a given exposure to	Some reasonable, scientific analysis must be provided if this assumption is to be retained. For example, a selection of initial fT4 values that differ substantially, e.g., the 10th, 30th, and 50th percentiles, should be run through the	S/M

			perchlorate would be expected to depend on the fT4 level prior to the exposure. Second, even with a specified fT4 level, individual responses to the specified exposure would be expected to differ. This is supported by the statement on page 7-5 that "intra-individual variance in fT4 may also be a factor affecting the tail of the distribution, about 10% of the population variance is made up of intra-individual variance (Andersen et al., 2002)." Both of these effects would be expected to spread the distribution as well as shift the median.	BDDR model with the addition of the same amount of perchlorate to demonstrate that the resulting "change" is consistent with the shift in the curve without any change in the shape of the curve.	
37	7.2	7-5	The analysis in this section, and therefore all of the conclusions therein, rely on the assumption that the shape of the distribution of fT4 remains constant during exposure to perchlorate. As mentioned in a previous comment, this assumption is problematic. No scientific justification is presented for this assumption that is counterintuitive.	Please provide a scientific justification or perform BBDR modeling to provide some basis for this assumption.	S/M
38	8.1 Hypothyroidism	8-1	It is stated that, "the human thyroid contains several months of T4 in the colloid". Is this statement based upon the results from Braverman et al. (2006), Laurence et al. (2000), or another study?	Please provide the relevant citation.	S
39	8.3 Other Potential Diseases	8-2	EPA states that the Comparative Toxicogenomics Database (CTD) has identified 455 diseases potentially assocated with perchlorate, but provides no discussion of what	Please describe the CTD findings more fully.	S

			those possible mechanisms of action are other than NIS inhibition or oxidative damage.		
40	9	Table 39	According to the equations on 6-6 and 6-7, as well as the discussion of the regression analysis, it appears that all analyses were of the ln(fT4). If this is an accurate interpretation of what was done, the last column of this table is either labeled incorrectly or is misleading or both. At best there is a linear relationship between the natural logarithm of fT4 and dose of perchlorate, in which case the "Dose of perchlorate per unit change in endpoint" will be highly dependent on the level of fT4 prior to the exposure to perchlorate. Thus, presenting the values in this column as a constant is inaccurate, as well as neither clear nor transparent. If the conclusions could be accurately portrayed in a table as simple as this one, we wouldn't need a BBDR mode.	Attempts to provide a simplistic conclusion to a complex analysis, such as those in Table 39, can be expected to be misinterpreted and misapplied by anyone who does not read and fully understand the complete document with all appendices. Especially the final column that implies a linear relationship between dose of perchlorate, change in fT4, and therefore, neurological effects, is simple, and simply incorrect. While such numbers can always be "calculated", the conditions that must apply in this case would take pages to describe. Therefore, without these qualifications, the table could be described as misleading or deceptive.	S
41	9 Conclusion	9-1	Stating: "the majority of studies identified support the notion that avoiding a shift in the proportion of the population at risk of hypothyroxinemia may avoid adverse neurodevelopmental outcomes" to justify this approach is not valid when the literature search was designed with this bias to find studies with positive results. See related comment above.	Please revise.	S
42	9. Conclusion	9-1	The following statement not consistent with our observations of EPA practices and our	Please correct or cite the guidance that describes the “more common approach”.	S/M

			knowledge of their guidance: "This is opposed to the more common approach of exploring the effect of a contaminant on a mean individual from a sensitive life stage." Per the EPA Benchmark Dose Guidance dated 2012 the practice is to use the lower confidence bound on a low response level, e.g., BMDL10 or BMDL5%, as the point of departure. The dose-response function used for this POD is usually that which either is or includes the most sensitive population. The mean, or more often the median, may be used when data are transferred among models, e.g., from the rat PBPK model to the human PBPK model, as it is the most certain and most stable data point. A much lower response is used from the final model.		
43	Appendix B	B-1	EPA has mentioned in the main document that the first trimester of pregnancy is the critical window in development in which thyroid hormones play a critical role. Steinmaus et al (2016) measured thyroid hormones in the second trimester approximately 8 to 13 weeks after their initial measurements of urinary perchlorate. The regression analysis by Steinmaus demonstrated the negative correlation of 1st trimester perchlorate urine levels with 2nd trimester fT4 and T4 but a positive correlation with TSH. Table B-2 failed to mention p values for those regressions, however. Perhaps the Project Baby's Breath protocol precluded 1st trimester blood draws.	There needs to be some explanation here of the relevance of second trimester thyroid hormone concentrations when the first trimester has been previously identified as the more critical time point.	S

44	Appendix B	B-4	The document states that the study used for the analysis, i.e., Steinmaus et al. (2016), "did not find a different relationship between perchlorate and fT4 or TSH between low and normal iodine intakes"" and therefore, "EPA calculated changes in fT4 and TSH using the all subjects iodine intake". However, EPA's hypothesis is that only populations that are deficient in iodine will be affected by exposures to low levels of perchlorate. Therefore, the data set that EPA believes is the most robust is in conflict with EPA's hypothesis.	This conflict requires resolution. Though the combined data might be justifiably used to develop parameters for the PBPK model, the fact that the data demonstrate that iodine deficiency does not increase the effects of perchlorate on thyroid hormones inherently conflicts with the modeling effort that describes an effect.	S/M
45	Appendix B	B-5	The beta estimate for the slope of the TSH function here is negative and falls outside of the range of the confidence intervals.	Correct the typographical error	E
46	Appendix B	B-6	EPA here assumes a baseline perchlorate dosage that is higher than the NHANES data but below that of Steinmaus et al (2016). The magnitude of the baseline is shown to have a significant effect on the overall effect of a particular perchlorate dose, but little to no explanation is given as to why the EPA assumes a lower baseline than Steinmaus. The combination of an artificially low baseline produces the "effect" of a change in the hormone levels based on the un-stratified data that was not observed in the analysis of the observed lack of effects of the study selected by EPA as the best data set.	Justification needs to be provided in regards to why this particular baseline was chosen.	S/M

47	Appendix C – Discussion	C-6	Here the case is made that there exists additional, unaccounted-for uncertainties in the relationship between fT4 and IQ. Are such uncertainties not addressed in the underlying literature, Korevaar et al. (2016)? EPA has made no attempt to explain the need for a predictive model between perchlorate exposure and IQ decrement. The effect slope is based on one Dutch study only, and the variability around that crucial beta estimate is quite high. It would be nice if EPA would supply references wherein these models have been previously used to predict adverse neurological effects through an intermediary hormone impacted by other, xenobiotic agents.	Further clarification about what exactly are these additional uncertainties and why they are not adequately addressed in the underlying literature is needed before resorting to Monte Carlo analysis.	S
48	Appendix C - Methods	Table C-5	According to this table, the effect measured by Korevaar et al (2016) is statistically insignificant with a high standard error. This calls into question the usage of fT4 and IQ data from Korevaar et al. (2016) because of the high amount of uncertainty surrounding the relationship between these two parameters.	Suggest that EPA provide an explanation for the use of non-significant effect estimate and how it relates to the inverted-U shape curve found in the original paper.	S
49	Appendix C	General	The premise of this appendix is to relate perchlorate exposure to an adverse neurodevelopmental outcome. In this case, a decrease in IQ of 1 point is considered such an outcome. The change of 1 IQ point does not appear at face value to be a significant effect. Korevaar says in a Dutch study that there's an inverted U-shaped association of maternal	This endpoint/critical effect needs to be evaluated by a developmental psychologist or another appropriate expert because it appears to be insignificant. Additionally, text needs to be included that describes the relative amount of risk associated with this effect, because it may be of more importance to some rather than others.	S/M

			thyroid function during early pregnancy with cognitive function, wherein both low and high maternal fT4 (but not TSH) concentrations during early pregnancy were associated with lower child IQ and lower grey matter and cortex volume by MRI scan. It seems there is an attempt to stretch the syndrome through de novo analysis of the Korevaar et al. (2016) data to say that the perchlorate effects on fT4 are enough to drop IQ by 1 point. But 1 point when the average is 100 would appear to be insignificant and we question the accuracy of measuring such differences. We were not able to include an expert in such measurement and testing in our review team and would defer to other external reviewers with such expertise		
50	General	All	The mechanism of action for perchlorate was determined by the National Research Council in 2005. If there is perchlorate exposure above the threshold for iodide inhibition, there should be no effect. The mechanism of action is being ignored in this report.	Include the mechanism of action in the analysis of hormones levels and neurodevelopment.	S/M

Environmental Defense Fund / Natural Resources Defense Council

November 19, 2017

Samuel Hernandez
U.S. EPA, Office of Ground Water and Drinking Water
Standards and Risk Management Division, (Mail Code 4607M), 1200
Pennsylvania Avenue NW.
Washington, DC 20460;

RE: Comments on EPA's Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water at Docket No. EPA-HQ-OW-2016-0438

Dear Mr. Hernandez:

The Environmental Defense Fund (EDF) and the Natural Resources Defense Council (NRDC) appreciate the opportunity to comment on the Environmental Protection Agency's (EPA) draft report on proposed approaches to inform the derivation of a maximum contaminant level goal (MCLG) for perchlorate in drinking water at Docket No. EPA-HQ-OW-2016-0438-0019.[1] EPA requested comments on the draft report in the September 15, 2017 *Federal Register* and extended the comment period to November 20, 2017 in the October 12, 2017 *Federal Register.*

With this latest analysis, EPA scientists address the central question raised by EPA's Science Advisory Board (SAB) in 2013, commenters (including NRDC and EDF), and the agency's peer review panel: what is the relationship between perchlorate exposure in the first trimester of pregnancy on a child's neurodevelopmental outcomes when the mother gets insufficient iodine in the diet. The issue is critical because almost half of US pregnant women get insufficient iodine, especially in the first trimester when they may not be yet aware they are pregnant and under a doctor's care. The SAB specifically requested that EPA consider the effects of low levels of free thyroxine (fT4), referred to as hypothyroxinemia, that had not resulted in an increase in thyroid stimulating hormone (TSH), rather than hypothyroidism where the low T4 had already triggered an increase in TSH levels.

From their review of literature, EPA scientists stated that:

> [E]arly in brain development, fT4 deficiency can affect neuronal cell proliferation and cell migration in the hippocampus (essential for learning and memory, cognitive function), cerebral cortex (essential for executive function, cognitive function), and the medial ganglionic eminence (transitory development structure responsible for guiding axonal migration) (G. Williams, 2008). Maternal hypothyroidism or hypothyroxinemia at these early stages may result in problems with gross motor skills and visual attention and processing (Zoeller & Rovet, 2004). As the first trimester progresses, increases in hCG [Human chorionic gonadotropin] result in a higher production of T4 and reduced TSH and TBG (Morreale de Escobar et al., 2007). In the fetus this period also corresponds to

[1] EPA Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water, September 2017. See https://www.regulations.gov/document?D=EPA-HQ-OW-2016-0438-0019.

> neurogenesis in the midbrain and cortex, neuronal migration into the cortex, deiodinase activity for conversion of T4 to T3, and presence of nuclear thyroid receptors in the brain (Morreale de Escobar et al., 2004).[2]
>
> Higher levels of maternal fT4 throughout pregnancy allow for normal neuron and glial cell migration and differentiation, axonal growth, dendritic branching, neurogenesis, and synaptogenesis to occur (G. Williams, 2008). The complex interconnectedness of brain regions required for normal function could be impaired by effects on all of these processes simultaneously or in sequence, and across multiple brain regions. Maternal thyroid deficiencies during these processes further affect visual processing, development of fine motor skills, IQ, and selective learning problems (Zoeller & Rovet, 2004; Zoeller et al., 2007).[3]

EPA scientists concluded that:

> Evaluating these results as a whole demonstrates that in different populations, at different ages for neurodevelopmental assessment, and at various cut points for fT4, there is a significant difference in performance on global cognitive tests when comparing the offspring of hypothyroxinemic women to those of non-hypothyroxinemic women (Costeira et al., 2011; Ghassabian et al., 2014; Júlvez et al., 2013; Korevaar et al., 2016; Li et al., 2010; Pop et al., 1999; Pop et al., 2003; Suárez-Rodríguez, Julián, and Aguilar, 2012).[4]

EPA's scientists also highlight that neurodevelopmental adverse outcomes other than cognition have also been found:

> Additionally, studies identified in the literature review . . . also associated maternal hypothyroxinemia with an offspring's increased risk of schizophrenia (Gyllenberg et al., 2016), ADHD (Modesto et al., 2015), expressive language delay (Henrichs et al., 2010) and other outcomes (Finken et al., 2013; Kooistra et al., 2006; Noten et al., 2015; Päkkilä et al., 2015; Román et al., 2013; van Mil et al., 2012).[5]

Based on the targeted literature search, EPA's scientists identified 55 studies assessing thyroid hormone levels and neurodevelopmental outcomes.[6] They narrowed the list to 29 studies, referred to as Group 2, which considered the relevant exposure window and were compatible with the Biologically Based Dose Response (BBDR) developed by the Food and Drug Administration (FDA) and refined by EPA. They further narrowed the list to 15 studies, designated as Group 1, which evaluated fT4 as a continuous or categorical measure. EPA concluded that:

ED_005043_00062727-00080

> Taken as a whole, the majority of the Group 1 studies imply that **neurodevelopmental impacts due to altered maternal fT4 levels or presence of maternal hypothyroxinemia occur.** In addition, the Group 2 studies (along with several Group 1 studies) also demonstrate adverse impact of maternal hypothyroxinemia on neurodevelopmental outcomes of the offspring. **Overall, the results of this literature review lend support to the concept that maternal fT4, especially in the hypothyroxinemic range, is critical to the offspring's proper neurodevelopment**. Across different age ranges and neurodevelopment indices, **the impact of altered fT4 is seen even with small incremental changes in fT4 (and in populations with fT4 across the "normal" range)**.[7] [Emphasis added]

EPA scientists developed two approaches to developing a reference dose.

- Quantified relationship between perchlorate exposure and maternal fT4 levels in early pregnancy and neurodevelopmental outcomes in children; and
- Estimated amount of perchlorate needed to increase the proportion of low-iodine individuals that will fall below a hypothetical hypothyroxinemic cut point by a define percentage.

Quantified relationship between perchlorate exposure and maternal fT4 levels in early pregnancy and neurodevelopmental outcomes in children.

EPA scientists characterized the relationship between perchlorate exposure and fT4 levels in mothers with low dietary iodine intake and how that exposure changes neurodevelopmental outcomes. Of the 15 studies in Group 1, EPA scientists identified five studies and four neurodevelopmental endpoints that were quantitatively connected to changes in fT4 levels in the first trimester for pregnant women with iodine intake of less than 75 micrograms per day (μg/day). The four endpoints were:

- **Psychomotor Development Index (PDI):** Assessment of fine and gross motor skills such as body control, coordination, and manipulation. It is the other main indices in BSID.
- **Mental Development Index (MDI):** Assessment of cognitive and language development using items related to sensory perception, knowledge, memory, problem solving, and early language. It is one of two main indices for assessing neurodevelopment in children in the Bayley Scales of Infant Development (BSID).
- **Standard Deviation of Reaction Time:** Assessment using the Amsterdam Neuropsychological Test computerized assessment program.
- **Intelligence Quotient (IQ).**

EPA scientists calculated the dose of perchlorate needed to result in a unit change in each of these neurodevelopmental endpoints. They predicted that:

- **PDI:** A dose of 1.7 micrograms of perchlorate per kilogram of body weight per day (μg/kg/day) was needed to decrease the index by one point using data from week 12 of pregnancy;
- **MDI:** A perchlorate dose of 2.2 μg/kg/day was needed to decrease the index by one point using data from week 12 of pregnancy;

[7] EPA Draft Report, Section 5.5, page 5-61.

ED_005043_00062727-00081

- **Reaction Time:** A dose of 3.0 µg/kg/day was associated with a one standard deviation decrease in reaction time using data from week 13 of pregnancy;
- **IQ:** Doses from 6.5 to 45 µg/kg/day were associated with a one point drop in IQ based on two studies with data from gestation week 16 and 13.[8]

Based on this method, the most sensitive endpoint appears to be PDI with IQ being the least sensitive one. It is worth noting that the estimates are based on a limited number of endpoints and health effects. In Section 8 of the report, EPA noted that there are additional potential adverse health effects that were not captured in the analysis to inform the derivation of a perchlorate MCLG.

Estimated amount of perchlorate needed to increase the proportion of low-iodine individuals that will fall below a hypothetical hypothyroxinemic cut point by a define percentage.

Recognizing the risks to a child's neurodevelopment from hypothyroxinemia, EPA scientists evaluated how much perchlorate exposure is needed to shift the proportion of the population that will fall below a hypothetical hypothyroxinemic cut point by 1% or 5%. In other words, how many thousands pregnant women will become hypothyroxinemic in the presence of perchlorate. They acknowledged that:

> This approach does not directly connect the BBDR output to neurodevelopment. However, for pregnant mothers in early pregnancy, this shift could be related to avoiding an increase in the offspring population's risk of adverse neurodevelopmental impacts given the preponderance of evidence located in EPA's literature review that finds an association between hypothyroxinemia and adverse neurodevelopmental outcomes . . .[9]

EPA's scientists defined hypothyroxinemia as the 10th percentile of fT4 of median-iodine intake population of 170 µg/day. The estimated fT4 values at the 10th percentile of a normal iodine intake population corresponded to about 50th percentile of a low-iodine intake population. In other words, approximately 50% of pregnant women with iodine intake less than 75 µg/day would already be hypothyroxinemic.

They predicted that a dose of:

- 0.3-0.4 µg perchlorate/kg/day is associated with a 1% increase in pregnant women with hypothyroxinemia; and
- 2.1-2.2 µg perchorate/kg/day is associated with a 5% increase in pregnant women with hypothyroxinemia.[10]

While these percentages appear small, they represent a significant number of potentially affected children since neurodevelopmental harm is likely irreversible. EPA did not estimate the number of pregnant women or children potentially affected. We did. Based on four million children born

[10] EPA Draft Report, Section 7.1, Table 35 and Section 9, Table 40.

ED_005043_00062727-00082

in the US each year,[11] an estimated 400,000 were born to women with hypothyroxinemia (10th percentile). A 1% shift in the population of women with hypothyroxinemia associated with perchlorate exposure would correspond to an increase of 4,000 impacted children; if there is a 5% shift, the number of children born to hypothyroxinemic mothers would increase to 20,000 impacted children. EPA also considered other percentiles to define hypothyroxinemia and came up with similar perchlorate doses of concern.

Exposure to additional goitrogenic chemicals should be considered.
We understand that EPA's analysis concerns perchlorate exposures. However, as clearly noted in its report, pregnant women are likely exposed to additional chemicals negatively affecting the thyroid gland's function. EPA stated that "[w]hile the BBDR model does not explicitly consider other goitrogens (e.g., thiocyanate, nitrate), simulating results for a mother with low iodine intake and low baseline fT4 may help to address the sensitivity of individuals with high exposures to other goitrogens."[12] We encourage the agency, and its partners at FDA, to continue improving the BBDR model to make it compatible with iodine levels below < 75μg/day to better represent these other exposures that affect the thyroid. Approximately 16% of American women have an iodine intake of 50 μg/day.[13] Until those refinements are made, EPA needs recognize the uncertainty through safety factors.

Safety factors are needed.
EPA clearly recognized the variability in fT4 as an important uncertainty factor in estimating perchlorate exposure associated with low fT4. Specifically, it stated that "…different populations vary widely in their distribution of fT4 levels;" there also are "intra-individual variance in fT4."

These intraspecies and intra-individual variation could be based on physiological fluctuations or due to the presence of other goitrogenic chemicals affecting the thyroid function. For these reasons, we recommend EPA apply at a minimum a safety factor of 10 to the most sensitive endpoints. For the first approach, EPA should use PDI as the most sensitive endpoint to provide a reference dose that would be 0.17 μg/kg/day. For second approach, the reference dose would be the 0.21 μg/kg/day to protect all but an estimated 20,000 affected children and 0.03 μg/kg/day to protect all but an estimated 4,000 affected children.

General observations on the process.
EPA scientists have risen to the challenge presented by the SAB, the previous review panel, and the public comments. They have conducted a rigorous analysis of the science and presented its findings in a coherent and clear manner. Having watched this process over the years, we wanted to take the opportunity to provide some general observations:

1. **EPA's scientists provide an essential service:** Academic researchers laid a solid foundation for the analysis. Without their work, typically funded by government grants, we would not have the evidence necessary to recognize the harm from perchlorate at the levels under consideration. But it took the independent scientists at EPA, building on a

ED_005043_00062727-00083

model developed by FDA, to provide the objective rigorous review of the evidence and adapt the model.

2. **Peer-review process works:** The agency rose to the challenge of two previous peer-review panels, one established by EPA's SAB and the other by EPA's Office of Water. The panels operated in a transparent process and provided independent and objective review of the analysis by EPA. We anticipate that this third and final panel will do the same. The integrity of the process depends on credibility of the experts on the panel. Screening out these experts because they receive government funding as EPA is now doing[14] is irresponsible and unlawful. It undermines the quality of the review and the credibility of the process.
3. **Incremental changes in free T4 (fT4) are fundamental:** Critical neurodevelopmental adverse effects could be missed by measuring full range maternal fT4. Windows of susceptibility are common in all organs during development. Hormonal control of brain development is no exception. Therefore, adverse neurodevelopmental outcomes will vary based on the time and duration of decreases in fT4 levels. We appreciate seeing the agency building a model based on this fundamental principle of developmental biology.

RE: Comments on EPA's Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water at Docket No. EPA-HQ-OW-2016-0438

Dear Mr. Hernandez:

The Environmental Working Group, a nonprofit research and advocacy organization based in Washington, DC, submits comments on the Environmental Protection Agency's draft report Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal (MCLG) for Perchlorate in Drinking Water.

Perchlorate exposure is of utmost concern for children's health because as of 2005-2010, the latest period for which data are available, more than half of all pregnancies in the U.S. were recorded for women with iodine intake below the WHO recommendation of 250 micrograms per day.[1] The EPA draft proposal represents a true step forward for protecting the health of American children from this toxic chemical that contaminates food and drinking water. EWG also wholeheartedly supports the detailed comments submitted by the Environmental Defense Fund and Natural Resources Defense Council.

In this letter, EWG highlights three main messages:

- The approaches for perchlorate MCLG derivation outlined in the draft report are scientifically sound and should be adopted for the final agency decision.

- The EPA should use a minimum tenfold safety factor when establishing a reference dose for perchlorate to account for human variability in thyroid vulnerability, and the prevalence of other goitrogens in water and food.

- The EPA's analysis conclusively demonstrates that the existing Reference Dose (RfD) of 0.7 ug/kg-day is not protective of public health and needs to be lowered.

Details and rationale for EWG's recommendations are provided below.

1. EWG supports the modeling and approaches outlined in the draft report.

EWG commends the Agency's modeling of perchlorate effects on the maternal thyroid gland in women with low iodine intake during pregnancy. EWG finds that the EPA has thoroughly reviewed the literature for both perchlorate effects on thyroid homeostasis, and synthesized a sizable body of literature linking thyroid perturbations during pregnancy and early life with altered brain development and motor control in young children. In our assessment, the EPA's method is rigorous, transparent, and appropriately evaluates perchlorate risks for the most vulnerable population and time periods, specifically with the additional focus on women with hypothyroxinemia during the first trimester of pregnancy.

2. EPA must use appropriate safety factors when determining acceptable perchlorate exposure.

While EPA's modeling is high quality and appropriately based on studies of perchlorate's effects on human pregnancies, important uncertainties remain. EWG is concerned that the draft EPA model may not capture the full variability of maternal response to thyroid perturbation, and does not account for women with pre-existing thyroid disease who may be more affected by perchlorate exposure.

EWG also notes that perchlorate intake does not occur in isolation. During pregnancy, women and the developing fetus are also exposed to other chemicals harmful to the thyroid. The EPA model did not explicitly account for the effects of concurrent exposures to certain goitrogens, such as thiocyanate and nitrate.

The EPA draft proposal has also neglected to consider chlorate, another goitrogen commonly detected in food and drinking water. Chlorate forms when drinking water is disinfected with hypochlorite bleach. Like perchlorate, chlorate is also formed when bleach degrades due to inadequate management conditions. If bleach is then used to disinfect food handling equipment and produce, both perchlorate and chlorate could contaminate food simultaneously, increasing the risk of harm to the thyroid. The European Food Safety Authority's 2015 assessment of chlorate bases its assessment of chronic exposure on the risk of iodine uptake inhibition, the same toxicity pathway that is affected by perchlorate.[2]

EWG urges the EPA to employ a minimum tenfold safety factor in the development of its reference dose for perchlorate to account for the outstanding uncertainties and to protect against the significant, lasting effects perchlorate exposure can have on children's brain and motor development.

3. Existing Reference Dose of 0.7 ug/kg-day is not protective of public health and needs to be lowered.

The reference dose for perchlorate exposure currently in effect was established by the EPA in 2005 and was based on a No Observed Effect Level (NOEL) reported in a study of thyroid function for healthy adult volunteers. The latest research conclusively demonstrates that data from non-pregnant adults, even with the use of additional uncertainty factors, does not adequately predict risks of thyroid hormone disruption during the sensitive life stages of gestation and childhood. Thus, the Agency's proposal to model effects of perchlorate exposures during pregnancy represents a true advance for children's health protection.

The EPA's draft released for comment in September 2017 presented two methods to evaluate adverse effects of perchlorate exposure. Both methods produced similar outcomes, demonstrating the overall robustness of the EPA proposal.

The EPA's first method assessed the impact of perchlorate on the circulating levels of free thyroxine, a thyroid hormone also called free T4 (fT4), in mothers with low dietary iodine. It identified four health endpoints that can be quantitatively correlated with maternal fT4 levels in pregnant women with low iodine intake. EWG recommends that EPA base its reference dose on the most sensitive outcomes associated with perchlorate exposure, a change in the infant Psychomotor Development Index. Exposure to 1.7 micrograms of perchlorate per kilogram of bodyweight per day during week 12 of pregnancy is expected to cause a one-point decrease in the Psychomotor Development Index in childhood. The reference dose and the future MCLG for perchlorate must protect against this type and degree of change in psychomotor development.

The EPA used a second method to determine the amount of perchlorate exposure that would shift additional American pregnancies towards the condition of hypothyroxinemia. The EPA defined the hypothyroxinemia cutpoint as the lower 10th percentile level of fT4 in a population with median iodine intake. The EPA's analysis points out that hypothyroxinemia during pregnancy is associated with poorer neurodevelopment in infants, including lower non-verbal intelligence, slower reaction times, non-verbal cognitive delays, as well as profound outcomes with life-long consequences such as schizophrenia, attention deficit hyperactivity disorder and autism.

The EPA draft report calculated that a dose of 0.3 - 0.4 ug/kg of perchlorate per day will cause a 1 percent increase in the number of pregnant women with clinically defined hypothyroxinemia, and a dose of 2.1 - 2.2 ug/kg per day will cause a 5 percent increase. The analysis jointly developed by the Environmental Defense Fund and Natural Resources Defense Council indicates this would impact 4,000 and 20,000 U.S. pregnancies, respectively.

The modeling EPA presented clearly indicates that the current reference dose for perchlorate is not protective of public health and must be lowered. Using any of the points of departure identified above, and applying a minimum tenfold safety factor will protect many thousands of pregnancies in the United States today and the health of American children.

In conclusion, EWG finds that the EPA scientists have successfully addressed the central question raised by EPA's Science Advisory Board in 2013 and the agency's peer review panel, regarding the relationship between perchlorate exposure in the first trimester of pregnancy and a child's neurodevelopmental outcomes when the mother has insufficient iodine intake.

Submitted on behalf of the Environmental Working Group,

Sonya Lunder, MPH, Senior Analyst

Olga Naidenko, Ph.D., Senior Science Advisor

Subject: Request for Public Comments To Be Sent to EPA on Peer Review Materials To Inform the Safe Drinking Water Act Decision Making on Perchlorate [82 FR 43354; September 15, 2017]

The National Aeronautics and Space Administration (NASA) appreciates the opportunity to review and comment on the "Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water (Volumes 1-3)." NASA reviewed the draft Report and is providing general and specific comments, including observations on EPA's Draft Charge Questions under separate review, to promote consistency and clarity for EPA's proposed submission for Peer Review.

EPA's Draft Report, supporting Draft Charge Questions, and Interim List of Peer Reviewers form the technical basis of EPA's efforts to obtain formal, independent peer review to guide future efforts in the establishment of a Maximum Contaminant Limit (MCL) for Perchlorate in Drinking Water. NASA provides its comments (attached) to support sound, defensible, science-based decision making. We understand that the purpose of this Report is to provide modeling capability that serves as the foundation of future regulatory actions. NASA strongly encourages EPA to focus this Report and its supporting documents to validate and strengthen critical aspects of the proposed model. Our comments address issues within the Draft Report and include suggestions for direction to the Peer Review Committee to address outstanding issues or concerns with the current draft Report.

NASA acknowledges and appreciates that EPA addressed numerous technical comments provided in an earlier public review of the proposed model and during peer review in January 2017. Our overarching comments and specific issues related to the current report are provided in Attachment A.

ED_005043_00062727-00091

NASA looks forward to continued cooperation with EPA to ensure safe and successful execution of our mission. If you have any questions concerning these comments, please contact Dr. Linda Wennerberg at 202-358-4558.

Sincerely,

Mike A. McNeill
Deputy Director, Environmental Management Division

- Ms. Grafton

NASA General/Systemic Comments on the Draft Report:

- EPA's decision to split public comment and review of the proposed Draft Report from the Draft Charge Questions and Interim List of Peer Reviewers is both troubling and confusing. The Agency's approach fragmented traditional public review and undercut the established method to target charge questions to consider areas of scientific disagreement or controversy and ensure appropriate expertise on the peer review panel. NASA found this artificial separation of key aspects of independent peer review concerning and requests that EPA integrate emerging public comments into the final charge questions for the peer review panel. EPA also needs to review the Peer Review Committee membership to ensure appropriate expertise upon the comments received during this public comment period. NASA's comments identify key issues for peer review consideration.
- NASA strongly encourages EPA to consider the in-depth and substantial technical input provided by the Department of Defense (DoD) and the Food and Drug Administration (FDA), due to their unique experience and expertise in the development of the proposed model and evaluation of impacts on human neurodevelopment. NASA concurs with this well-supported technical input provided in comments to the docket by experts in these and other Federal Agencies. We support this public review to strengthen EPA's modeling efforts to develop a scientifically defensible MCL for perchlorate.
- The input from experts within DoD and FDA is especially critical as EPA has not provided an independent validation of the model or its underlying assumptions. The lack of model validation and transparent understanding of the intricacies of this proposed model, such as its underlying assumptions, handicap ready public review. The complexity of the Draft Report and its lack of transparency compound difficulties in rapid and informed public review and comment. Again, EPA is encouraged to consider expert input on the model from its fellow Federal Departments and Agencies, as well as the public.
- The lack of targeted behavioral or social science expertise within EPA or on the proposed Interim List of Peer Reviewers, including population statisticians and clinical psychologists, raises significant questions due to the stated Draft Report focus on neurodevelopmental impacts. Neurodevelopmental studies vary significantly by design, methodology, definition, and analysis. Such studies often generate controversy and disagreement, especially when considering very low levels of impact, such as the change in one IQ point. EPA provides little clarity on the choice of individual neurodevelopmental studies or their applicability for specific perchlorate exposures. EPA does not provide substantiation that supports treating a diverse set of outcomes as related endpoints. NASA strongly encourages EPA to include clear charge questions and also appropriate expertise to ensure a more defensible peer review and model formulation.
- EPA intends to use this proposed model to estimate the impacts of perchlorate exposure on identified sensitive subpopulations and subsequent neurodevelopmental impacts. This dose response approach relies heavily on

literature targeting a controversial clinical pre-condition (not a disease state) of hypothyroxinemia in women in early stages of pregnancy. The choice to focus on hypothyroxinemia, a clinical designation that is subject to interpretation, fuels concerns as EPA applies conservative assumptions and uncertainty considerations in the interpretation of the model and literature results. This broad area of concern necessitates the need for clear direction to the peer reviewers to evaluate EPA's proposed approach.

- NASA notes that the EPA Science Advisory Board (SAB) directed EPA to consider this conservative state in the pregnant woman and focus on the more sensitive first trimester of pregnancy after the first January 2017 peer review. The SAB also stated that EPA should use a Biologically Based Dose-Response (BBDR) model approach (referred to as the proposed model). EPA needs to ask the proposed peer review to review and comment on whether EPA adequately addressed the January 2017 peer review direction and if the proposed Draft Report and BBDR model are appropriate and scientifically defensible. In review of this Draft Report, NASA finds EPA does not adequately evaluate whether previous SAB and January 2017 peer review comments have been addressed. A charge question directing the Peer Review Committee is most appropriate.
- The bulk of the Draft Report focuses on a literature review, starting with 55 studies and the detailing of the final 5 studies selected to support the model. EPA devotes significant attention to detailing the studies in the literature review but limited discussion on how these studies inform the derivation of an MCLG or the underlying assumptions and determinations by EPA. EPA offers scant clarification of the uncertainties and clear relationships between the chosen studies and the proposed model. The lack of specificity in this crucial basis of the Draft Report should be considered more in-depth by the peer reviewers.
- EPA appeared to select only studies with positive impacts and not to use studies that did not demonstrate a direct relationship.
- EPA acknowledged that it relied on EPA's own digitization of data from figures in key studies and lacked direct evaluation of the supporting data, potentially impacting on the analysis of uncertainty and other factors.
- The process EPA lays out to actually use those 5 studies for predictions from the proposed BBDR model, the derivation of the distribution of fT4 (to correlate hormone levels and potential impacts to a developing fetus), and then the relationship for fT4 and specific neurodevelopmental impacts again gets limited discussion or explanation in the Draft Report. The reader is left with a very disjointed understanding, which reads that one set of events happen, then other events happen, and then EPA is able to make definitive statements on how doses of perchlorate relate to potential neurodevelopmental impacts. EPA does not adequately delineate how the studies inform the model or define how the progression of exposure to a defined impact occurs. Confounders, such as the presence of other goitergens or smoking in the pregnant woman, are simply ignored. The overall progression of exposure, dose, and result are not clearly

defined in the Draft Report and should be subject to focused peer review evaluation and direction.

- EPA is strongly encouraged to review and correct assertions and language throughout the Draft Report that is incorrect or inaccurate. Draft Report language contains errors and contradictions that confuse and mislead the reader. Examples include false attribution to the National Academy of Sciences (NAS) report (2005) that "main source of perchlorate is rocket fuel, by both the defense and aerospace industries". In fact, the NAS noted that assessment from a draft EPA report but declined to support EPA's draft language. In Chapter 8, "Other Health Effects Potentially Associated with Perchlorate", EPA repeatedly identifies potential health effects but then later states that there is no proof that perchlorate actually causes these health effects. NASA requests EPA remove inaccurate or misleading statements to minimize confusion for the peer reviewers and the public. Chapter 8, in particular, offers unsupported statements that do nothing to support sound model development in the Draft Report and simply offer confusing, inflammatory statements. NASA requests EPA remove Chapter 8, as it offers no support for the model development or derivation of an MCL, or direct the Peer Review Committee to not review and comment on this Chapter.
- In addition to the need for EPA to review and reduce confusing or inaccurate statements throughout the document, sizable amounts of the Draft Report discuss alternative studies or efforts that do not support the SAB direction for the BBDR model development. Extensive discussion of alternative approaches, such as those authored by Steinmaus, in the Appendices B and C, serve to confuse the reader and distract from the stated purpose of the Draft Report while offering little substance to implement the SAB's direction to EPA. NASA concurs with EPA's decision not to address any of these distracting alternatives in the initial draft charge questions; however, we also request EPA either edit the Draft Report to clarify the focus specifically on the SAB direction and the development of a defensible BBDR model or to direct the peer reviewers to not review or consider these alternative approaches. Inclusion of such alternatives does little to support model development and offers a significant distraction from the stated SAB direction.
- The overall thrust of the proposed BBDR model is the estimation of the dose and impacts from perchlorate exposure on the identified sensitive subpopulation. A very limited set of studies directly addressed dosage of perchlorate and EPA provides little clear discussion of how dose-response relationships clearly link perchlorate to the targeted neurodevelopmental effects. EPA's chosen studies point to the potential for alterations in thyroid hormone levels to lead to impacts in human neurodevelopment. Again, the Draft Report focuses extensively on a literature review but provides limited discussion of key assumptions, assessment of uncertainties, and the clear mechanisms in the proposed model to estimate perchlorate dose-response impacts on neurodevelopment in humans.
- EPA is silent on declining levels of perchlorate in water and other environmental media. The potential for exposure, especially at low doses, raises the question if

this proposed model and EPA's assumptions reflect that actual state of low levels of perchlorate in the environment.

NASA Specific Comments:

- Again, NASA concurs with technical comments and issues identified by DoD and FDA with the proposed model and the utilization of studies on neurodevelopmental impacts. EPA is encouraged to consider the expertise and input from Federal Agencies.
- Page 1-3: EPA discusses contradictory studies that directly relate to perchlorate exposure but does not provide clear direction on how these contradictory studies support the proposed model. NASA requests that EPA provide clearer direction to the Peer Review Committee to evaluate the applicability of these studies and others to support model development.
- Page 1-4: EPA discusses efforts to establish a Health Reference Level (HRL) but does not include any discussion of attributes from the NAS Report (2005) that formed the basis of the IRIS value for perchlorate. EPA is encouraged to provide a summary of the NAS determination for consideration and completeness,
- Pages 2-6 to 2-8, 3-15: The issue of other goitergens, such as isocyanate, and exposure to environmental contaminants, such as endocrine disruptors, or behaviors, such as smoking, serve as potential confounders to the production of T4 by the thyroid is identified. However, EPA does not provide resolution on the issue of confounding. Again, EPA is encouraged to request peer review direction on this matter to support a more robust Mode of Action approach, building on previous efforts by NAS.
- Pages 3-5 to 3-9, 3-16 to 3-18, 4-6: EPA provides a summary of key model parameters but does not also provide independent model validation or substantive explanation of key assumptions or fundamental uncertainties. Validation of this model and the delineation of assumptions are critical to model review. EPA needs to directly address these issues in charge questions and through the sharing of the model to the Peer Review Committee.
- Pages 5-1 to 5-17: Peer review needs to expressly review EPA's approach to implement the SAB direction to "identify literature and conduct analysis to support the model outputs for the downstream effects". Key assumptions on the process to assign compatibility of studies for inclusion, limitation of the review, and selection of downstream effects form the basis of EPA's analysis. EPA's approach consolidates a range of assumptions, study choices, and a diverse set of outcomes (such as autism, ADHD, and neurodevelopmental measures) not readily linked.
- Pages 5-8 to 5-61, Appendix G: Focused peer review is needed to evaluate EPA's methodology, grouping, and interpretation of key studies, especially as EPA intentionally targeted studies that identified correlation with a range of neurodevelopmental outcomes. NASA identified this concern in our General/Systemic Comments, as well as the need for specific expertise in the

assessment of development, execution, and interpretation of neurodevelopmental studies.

- Pages 6-5 to 6-6: EPA assumes an inherently more conservative stance by focusing its analysis on the lower range of the distribution. This approach and other conservative assumptions raise the potential for skewing the choice and application of study results in the derivation of the MCLG. NASA noted this concern under the General/Systemic Comments and requested peer review of EPA's methodology.
- Pages 6-14 to 6-17: EPA provides limited discussion of key assumptions and methodologies to identify and address uncertainty to EPA's approach and the actual model development. This issue, previously noted under General/Systemic Comments, requires directed peer review on key aspects of definition of population, endpoints, estimated Iodine intake, and the process of maternal fT4 measurement. These issues are the foundation of assumptions driving the proposed model and EPA's limited discussion highlights the need for in-depth peer review and guidance.
- Page 6-19: EPA provides a limited explanation of its methodology to address significant confounding and interacting variables, and other screening factors in study selection. Again, NASA requests that EPA's methodology be evaluated in the peer review.
- Pages 7-1 to 7-2: The diverse set of targeted neurodevelopmental endpoints and EPA's methodology to connect shifts in fT4 to specific neurodevelopmental indicators merits peer review and assurances to include applicable technical expertise in the evaluation of such studies. Again, EPA provides limited discussion of uncertainties, the impact of other goitergens, and Agency assumptions on these critical relationships.
- Page 7-4 to 7-6: EPA addresses broadly, and with limited discussion, significant uncertainties on the hypothyroxinemia condition and its implications for early pregnancy mothers. EPA's discussion is confusing and truncated. Peer review must evaluate these critical EPA assumptions and decisions impacting on model development.
- Pages 8-1 to 8-3: EPA is strongly encouraged to remove this confusing Chapter to minimize its conflicting discussion and minimize confusion. This issue, previously identified in General/Systemic Comment, highlights the need for EPA to address the direction from the SAB for model development and assessment.
- Pages 9-1 to 9-2: EPA's summary of conclusions into two tables would benefit from clear and more detailed description, outlining the Agency's conclusions that form the basis of informing of an MCLG.

RE: FEDERAL REGISTER NOTICE [EPA–HQ–OW–2016–0438; FRL–9967–69–OW (SEPTEMBER 15, 2017)]

Dear Acting Assistant Administrator Shapiro:

The Perchlorate Study Group (PSG) has worked with the U.S. Environmental Protection Agency (EPA) for 20 years studying potential health effects from perchlorate exposure. From funding research to providing scientific comments and meeting with the Agency, we have consistently supported using the best available science to determine whether perchlorate should be regulated under the Safe Drinking Water Act. It is in this context that we offer the attached comments on EPA's *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water (Draft Report).*

The PSG supports EPA's decision to use a Biologically-Based Dose Response (BBDR) model to identify potential impacts from perchlorate exposure at relevant life stages. The PSG concludes that this approach, when developed with all critical clinical thyroid parameters and validated in a transparent manner, constitutes the best available science for addressing areas of uncertainty for the pregnant woman and her fetus. This approach has been endorsed by the National Research Council (NRC)[1] perchlorate panel and the 2013 EPA Science Advisory Board (SAB) perchlorate panel. *Moreover, when the most sensitive population is protected, all other populations are protected.*

The BBDR model has been improved significantly since the first peer review earlier this year. Additional work would improve the model even further to achieve our shared goal of ensuring that any perchlorate regulatory decision is based on the best available science. Specifically, various model inputs are overly conservative and, as a result, the model predicts potential impacts from perchlorate exposure that are extremely unlikely. While using conservative inputs may be best practice for conducting environmental risk assessments, it is not best practice for model development. Model inputs should be as realistic as possible to produce results that are as realistic as possible.

[1] National Research Council, *Health Effects of Perchlorate Ingestion*, Jan. 2005.

Even with these overly conservative inputs, however, the model buttresses the conclusion that no adverse health effects occur from perchlorate exposure at levels found in the environment, which are generally less than 4 ppb. In clinical studies, no *measurable* effects occur with perchlorate exposures of 245 ppb or less.[2]

We also see clear indications of bias in the Draft Report's literature search relative to identification of studies investigating potential neurodevelopment impacts from perchlorate exposure. Notably, EPA selected only five studies that found an association ("positive studies"). At the same time, EPA ignored seven studies that reported no association. While this weight of evidence should not be overlooked in EPA's analysis, even this biased approach leads to the same conclusion: *EPA's assessment does not demonstrate adverse health effects atexposure levels greater than the EPA reference dose (RfD).*[3] This conclusion is also supported by a robust set of animal studies that consistently demonstrate no significant changes in neurodevelopment at perchlorate concentrations much higher than environmental levels.

The BBDR model appears to be fit-for-purpose in supporting a determination that perchlorate does not cause adverse health effects at environmentally relevant concentrations. However, given the shortcomings noted here and in the attached technical comments, the model is not fit-for-purpose in deriving a numerical Maximum Contaminant Level Goal (MCLG). Further development and refinement of the model would be necessary to achieve this goal. This latter issue is largely moot, however, because the overwhelming weight of evidence from six decades of perchlorate research strongly supports the conclusion that there are no adverse neurodevelopmental effects from exposure to perchlorate at environmental levels.

In addition to these overarching issues, we recommend EPA address the following concerns and submit them to the second peer review panelists for their consideration:

- EPA should follow the NAS recommendations in its 2011 and 2014 reports on the IRIS program for conducting systematic review, evidence evaluation, and evidence integration. Other critical studies are available that the Agency should include as part of its scientific review over and above those considered by EPA in the Draft Report.

- EPA's decision to focus on hypothyroxinemia as a critical endpoint is not supported by the best available science or by public health professionals in the field. Hypothyroxinemia is merely a research construct; it is *not* a recognized medical condition treated by clinicians. The NAS 2005 perchlorate panel identified the pregnant woman with hypothyroidism as the most sensitive population based on the best available science. Accordingly, EPA should abandon further consideration of the hypothyroxinemia endpoint.

---

[2] The lowest reported No Observable Effect Level for a non-adverse effect was reported in Greer et al. (2002) as 7 µg/kg-d. This is equivalent to 245 ppb in water assuming a 70-kg adult drinking 2 L/d.
[3] The RfD is equivalent to 24.5 ppb in drinking water assuming a 70-kg adult drinking 2 L/d. The RfD includes an uncertainty factor to account for all sensitive populations.

- The PSG concurs with EPA's decision not to include the approach presented in Appendix C for further consideration by the peer review panel or by the agency. The use of a single epidemiological study, rather than the BBDR model, is not scientifically valid for purposes of making a perchlorate regulatory determination, much less for derivation of an MCLG.

- As noted in the letter from Intertox on October 6, 2017, the PSG also urges EPA and Versar, Inc. to ensure that the second peer review panel includes all relevant areas of scientific expertise necessary for conducting a comprehensive review of EPA's proposed MCLG approaches presented in the Draft Report.

- The PSG disagrees with inclusion of the information contained in Chapter 8 of the Draft Report. With the exception of hypothyroidism, which we agree is a potential (although undocumented) adverse effect of perchlorate exposure at sufficiently high doses, the other hypothesized endpoints have not been reported to be caused by perchlorate exposure.

The PSG appreciates EPA's consideration of our comments, and we look forward to a rigorous second peer review process and thoughtful analysis of the above and attached issues.

Sincerely,

Jason Leuck

EXECUTIVE SUMMARY

The US Environmental Protection Agency (EPA) is considering approaches to develop a perchlorate Maximum Contaminant Level Goal (MCLG). On September 15, 2017, EPA published a notice announcing the release of materials for public comment in the Federal Register (EPA–HQ–OW–2016–0439; FRL–9967–70–OW). The Agency has proposed a scientific review that requires the expertise of at least three diverse scientific disciplines. These are Biologically-Based Dose Response (BBDR) modeling, thyroid endocrinology, and neurodevelopmental testing. Aspects of these three disciplines have been integrated to develop two approaches to inform MCLG development. Although the purpose is unclear, an exercise is presented in Appendix C that might also be construed as an approach. We have reviewed these approaches and the underlying science and present our comments to EPA and the Peer Review Panel in this document.

BBDR Modeling

The BBDR model was improved following the first Peer Review. We commend the Agency for exploring the use of BBDR models to understand aspects of toxicology where data are not available. The current Reference Dose (RfD) for perchlorate is based on a *non-adverse* effect with an uncertainty factor (UF) to account for the most sensitive population, pregnant women. We recognize the utility of using EPA's model to inform on an *adverse* effect in the most sensitive population, thus obviating the need for any UF. However, the documentation of the model continues to be incomplete. For example, predicting the effects of iodine deficiency in the absence of perchlorate exposure is a fundamental task for this model. The ability of the model to accurately predict epidemiological data on iodine deficiency in pregnancy has not been demonstrated. Additionally, decisions were made to increase the conservatism of the model (e.g., using a weak TSH responder as the model subject). Thus, while the model does not provide outputs for an average pregnant woman, these outputs are later considered the mean of the distribution.

A scientifically-sound and transparent model can help inform the MCLG process. We recommend the Agency improve the transparency, present validation of the model, and provide a clear understanding of the model limitations.

Hypothyroxinemia

The output of the model is used to define a population of pregnant women as hypothyroxinemic, which is not scientifically defensible. The 2012 Science Advisory Board (SAB) recommended that EPA focus on "thyroid hormone perturbations and potential adverse neurodevelopmental outcomes from perchlorate exposure." There were no thyroid endocrinology clinicians on the SAB panel that suggested using hypothyroxinemia as an adverse endpoint. Based on the SAB's report, EPA has essentially adopted a new mechanism of action (MOA) for perchlorate despite widespread acceptance of the MOA described by the NRC (2005), which identifies hypothyroidism as the first adverse effect due to perchlorate. There are no studies reporting that perchlorate causes isolated hypothyroxinemia in pregnancy, which is EPA's proposed MOA. In fact, studies of first trimester pregnant women repeatedly report no association between perchlorate and thyroid hormone levels. Notably, just prior the first Peer Review meeting, the American Thyroid Association (ATA) published its authoritative guidelines on care during pregnancy and recommended no treatment of hypothyroxinemia in pregnancy.

We recommend the Agency use hypothyroidism as the adverse effect in the BBDR model.

Neurodevelopmental Testing

ED_005043_00062727-00105

The use of neuropsychological testing for the prediction of neurodevelopmental outcomes based on fT4 is not scientifically defensible. The Agency proposes multiple endpoints that are controversial from a scientific standpoint. Neurodevelopmental tests were developed to identify individuals with clear disability. The Agency has based its assessment on the mathematical relationships represented in five studies that reported effects caused by dramatically different doses of perchlorate. These studies were conducted in populations unlikely to be relevant to US exposures. More importantly, these studies lacked sufficient consideration of confounders, and lack sensitivity and specificity to detect small individual differences. EPA used only studies that reported an association and excluded a larger number of studies that did not. Lastly, EPA did not include discussion of animal studies that reported no impact from perchlorate exposure on a wide variety of neurodevelopmental outcomes.

The literature supporting the association between hypothyroxinemia and adverse neurodevelopmental outcomes is equivocal at best, and lacks the predictive power necessary to form the basis of a regulation. Consistent with the established perchlorate MOA and the weight of scientific evidence, the Agency should consider neurodevelopmental effects as downstream from hypothyroidism.

Conclusion

We have consistently supported the use of a BBDR model that is transparent and scientifically sound. We are pleased that EPA has proceeded along this track and encourage its continued improvement for use in this process. It is clear that the research available on hypothyroxinemia and the association to neurodevelopmental outcomes is not sufficiently robust for use in a predictive manner to provide the basis of a nation-wide drinking water regulation.

It is noteworthy that, despite the conservatism in the BBDR model, it predicts that doses of perchlorate well in excess of environmental levels produce only small changes in fT4. For example, the model predicts that in an iodine deficient 12-week pregnant woman, a small fT4 change from 8.85 pmol/L to 8.27 pmol/L requires a perchlorate dose of 10 μg/kg-d (equivalent to a drinking water concentration of 350 ppb on a daily basis). The current RfD is 0.7 μg/kg-d and drinking water concentrations rarely exceed 4 ppb. Clearly, the model suggests the current RfD is health protective of even the most sensitive populations.

The 2012 SAB urged EPA to consider sensitive life stages, use a model to estimate iodide uptake inhibition, use empirical observations to relate iodide uptake inhibition to thyroid hormone perturbations, and consider specific adverse effects on brain development. EPA has developed a model to consider an effect in the *most* sensitive life stage. By evaluating hypothyroidism, EPA could develop an MCLG that would prevent any adverse neurodevelopmental outcome as this is a recognized downstream effect based on NRC's MOA.

In developing health-based guidelines for the nation's drinking water, EPA has an exceedingly important job and one that must always be based on the best available science. We appreciate the clear effort in the improvement of this model with each iteration and continue to believe in its potential utility in informing the MCLG.

ED_005043_00062727-00106

1.0 INTRODUCTION

In June 2016, the US Environmental Protection Agency (EPA) stated:

> EPA is considering deriving a perchlorate MCLG [Maximum Contaminant Level Goal] by linking BBDR model output to alterations in thyroid hormone status that result in alterations in neurodevelopment. The draft approach for deriving a perchlorate MCLG outlines an assessment of the literature linking alterations in thyroid hormone status to alterations in neurodevelopment. Based on the results of this literature review, the report describes potential approaches to set the MCLG based on the availability of the current literature and the output of the BBDR model, predicting the effects of perchlorate on serum thyroid hormone concentrations in infants exposed via ingestion of formula mixed with contaminated drinking water or breast milk (see 81 FR 10617, March 1, 2016).

On September 15, 2017, EPA published a notice announcing the release of materials for public comment in the Federal Register (EPA–HQ–OW–2016–0439; FRL–9967–70–OW). EPA released the following documents:

- *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water* (Volume I – Main Report)
- *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water* (Volume II – Appendix A)
- *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water* (Volume III – Appendices B-G)
- *Requests for Comments: Interim List of Perchlorate in Drinking Water Expert Peer Reviewers and Draft Peer Review Charge Questions*
- *Revised Perchlorate BBDR Model - Code Information*

Prior to this submission, Intertox commented on the charge questions and the list of peer review candidates to EPA's managing contractor, Versar, Inc. (Provided as Appendices A and B).

EPA has presented three general approaches to an MCLG. Two approaches are detailed in the main document. However, a third option is presented in detail in Appendix C of the EPA report. It is unclear why this approach is presented as an appendix. However, we evaluate it, nevertheless, on the off chance that it is intended to be a serious approach.

In summary, these are the three approaches.

> Approach 1: The Biologically-based Dose Response (BBDR) model is used to estimate maternal free thyroxine (fT4) levels with different intake levels of iodine and perchlorate. A change in fT4 is used to predict neurodevelopmental deficits in offspring based on epidemiological studies.
>
> Approach 2: The BBDR model is used to predict a population shift comparing the number of women who would be considered hypothyroxinemic.
>
> Approach 3 ("Appendix C"): The results of a single epidemiological study are used to predict a relationship between perchlorate and maternal fT4. A change in fT4 is used to predict neurodevelopmental deficits in offspring based on epidemiological studies (only one study is used as a demonstration).

ED_005043_00062727-00107

The Perchlorate Study Group (PSG)[1] requested Intertox to review and provide scientific comments on the documents listed above. We will discuss the common and overarching topics (Section 2.0), the three approaches for use in developing a MCLG (Section 3.0), other issues (Section 4.0), and consideration of other goitrogens with the same mechanism of action (MOA) (Section 5.0).

2.0 OVERARCHING TOPICS

As noted in Section 1, we list the three general approaches are presented by EPA for use in deriving an MCLG. In this section we address commonalities that carry through all approaches. We discuss the scientific merit of: the BBDR model, hypothyroxinemia as an endpoint, the use of neurodevelopmental testing studies to predict changes in outcome with changes in fT4, and consistency with the clinical data.

2.1 EPA's Revised BBDR Model

EPA's first version of the BBDR model was Peer Reviewed in January 2017 with a final Peer Review report released in March of 2017. While the BBDR model has been revised since the previous version, we reviewed the revised BBDR model and find that, as a result of multiple overly-conservative inputs, it over-predicts the health impacts of perchlorate exposure. BBDR and physiologically-based pharmacokinetic (PBPK) models are tools that should accurately predict human physiological events which they are intended to characterize. Unlike a risk assessment, which errs conservatively to be health protective, a model should not contain multiple conservative inputs. These compounded inputs will result in an uncertain amount of conservatism that is unrealistic.

The models should accurately predict relevant and critical clinical parameters, the same ones that thyroid endocrinologists use to diagnose a disease. In the case of the thyroid, the American Thyroid Association (ATA) regularly publishes and updates science-based guidelines on the diagnosis and treatment of disease in pregnancy (ATA, 2017). The model should produce relevant information such that the variables that are commonly used to assess thyroid-related disease are predicted. After the development of a model, the Agency then decides whether the contaminant in question needs to be regulated to protect the public health. If necessary, it can apply—in a transparent manner—"safety factors" or adjustments to the output.

We concurred with the Peer Review panel that several necessary aspects were missing from the BBDR model. That is: 1) TSH feedback; 2) focus on the first trimester pregnant woman; and 3) include other goitrogens in the assessment. We are pleased to see that the former two have been integrated into the revised model.

In addition, we previously implored EPA to increase transparency in the studies used to define model inputs, the effect of changes to the model, and what steps were taken after the sensitivity analysis and model validation as it was unclear whether there were any changes based on these activities. We continue to recommend these to EPA with the revised model.

One of the most important issues we noted in January and continue to request is a demonstration that the model is in accordance with the known MOA for perchlorate. That MOA, laid out by the NRC (2005) identifies IUI as the first measureable effect; if IUI is sufficiently high and for a long enough duration, only then could the first adverse effect (hypothyroidism) occur. EPA's previous model reported changes to thyroid hormones that occurred before IUI. There is no study to support this

[1] The Perchlorate Study Group is supported by Aerojet Rocketdyne, American Pacific Corporation, Lockheed Martin, and Orbital-ATK.

ED_005043_00062727-00108

outcome. The current model should be examined to determine whether IUI occurs at a dose that is both consistent with the literature or occurs at doses lower than changes in thyroid hormones. This threshold provides a lower limit below which changes in thyroid hormone would not occur.

2.1.1 Iodine intake

EPA's expanded range of iodine intakes is appreciated. We have two issues of concern. First is that the lower levels have greater uncertainty due to the underlying data sets. The model has not been demonstrated to be able to predict iodine deficiency. There are study populations available for this critical check on the model (New Zealand, etc.).

The results of the BBDR highlight that the greater public health issue is iodine deficiency in pregnancy rather than perchlorate exposure. Studies have repeatedly demonstrated that perchlorate exposure contributes less than 2% of IUI given a normal diet that includes nitrate and thiocyanate.

Second is that, in setting regulatory levels for other contaminants, EPA has never used a nutritionally-deficient population as the most sensitive subpopulation. The results of the BBDR highlight that the greater public health issue is iodine deficiency in pregnancy rather than perchlorate exposure. Studies have repeatedly demonstrated that perchlorate exposure contributes less than 2% of IUI given a normal diet that includes nitrate and thiocyanate (Bruce *et al.*, 2013; Tarone *et al.*, 2010) and remedying iodine deficiency would have the greatest impact on public health (OIG, 2010). The EPA Draft Report (2017) recognizes the impact of iodine intake compared to perchlorate:

> …there is a significant drop in fT4 and increase in TSH with decreased iodide intake in the absence of perchlorate exposure. Comparing the predicted fT4 and TSH levels at zero dose of perchlorate in Table 2 (170 µg/day iodine intake) and Table 3 (75 µg/day iodine intake; a 56% drop in iodine intake from the median level) shows approximately a 16 to 17% drop in fT4 and between approximately a 44% to 58% increase in TSH, depending on the gestational week of interest.

There is a high correlation between iodine intake and perchlorate intake (Steinmaus *et al.*, 2016; Lee *et al.*, 2017). The assumption of iodine intake for modeling is used independently of realistic perchlorate exposures. In reality, it's not likely to have high perchlorate and low iodine intake on a regular, daily basis because intake is so highly correlated. These assumptions lead to unrealistic modeling results that are overly conservative.

2.1.2 TSH feedback

The hypothalamic-pituitary-thyroid axis is a tightly controlled hormonal negative feedback loop. It was an omission from the original model that we noted. The TSH feedback loop was added to the revised model. Although it is likely that actual feedback in a human is more nuanced and variable than the modeled feedback, EPA notes,

> Additionally, Hadlow *et al.* (2013) demonstrated that the relationship between TSH and T4, while a consistently decreasing function, is variable across the population with factors such as genetics, subclinical thyroid disease, age, and gender contributing to this variability. Thus, the ability of the thyroid to respond to TSH after perturbation by perchlorate probably varies across the population. The association between perchlorate and diminished T4 in the face of elevated TSH (Steinmaus, *et al.*, 2013; Steinmaus, *et al.*, 2007; Blount *et al.*, 2005) suggests that certain segments of the population (low iodide, smokers) respond more weakly than others.

ED_005043_00062727-00109

Our main concern is that the modeled individual has a high TSH and average fT4. This models a person who responds more weakly to TSH. EPA states, "this choice is based on an assumption that sensitive individuals with high TSH and average fT4 exist because the stimulus strength of TSH is proportionally weaker." Although this person may exist, the purpose of the BBDR is to estimate the response of an average person. As described in Chapter 4.0 of the EPA Report, the model output is used as the average value and a distribution is predicted around that average individual. A model should not contain multiple conservative inputs as this will lead to an uncertain amount of conservatism that is unrealistic.

2.1.3 Recommendation

A scientifically-sound and transparent model can help inform the MCLG process. We recommend the Agency improve the transparency, present validation of the model, and provide a clear understanding of the model limitations.

2.2 Hypothyroxinemia

Neither the NRC, nor any other authoritative body, lists hypothyroxinemia as precursor to hypothyroidism.

EPA has chosen to use hypothyroxinemia as an endpoint based on the recommendation of its Science Advisory Board (SAB). The purpose of the SAB was to evaluate approaches that EPA was exploring for use in developing an MCLG. No thyroid endocrinologists were members of this expert panel, which perhaps explains why the panel established as an endpoint a concept that is little more than a research construct. The ATA, in its *2017 Clinical Guidelines for the Diagnosis and Management of Thyroid Disease during Pregnancy and the Postpartum* states "Isolated hypothyroxinemia should not be routinely treated in pregnancy." In contrast the NRC's evaluation of perchlorate in 2005 included several thyroid endocrinologists who were very clear in their determination that hypothyroidism was the critical adverse effect for perchlorate exposure. There is no new scientific information that would tend to undermine NRC's conclusion.

Neither the NRC, nor any other authoritative body, lists hypothyroxinemia as precursor to hypothyroidism. The Agency has modified the accepted MOA for perchlorate. We are not aware of any perchlorate study, animal or human, where hypothyroxinemia is a measured endpoint to support this modification.

Finally, the BBDR model can only predict levels of total T3 (TT3) and total T4 (TT4). Although fT4 is not mechanistically modeled, EPA uses a fraction of TT4 to define fT4 levels. Diagnoses based on thyroid hormone measures are well-defined clinically. Subclinical hypothyroidism is elevated TSH with normal levels of fT4. Hypothyroxinemia is defined as low fT4 with normal levels of TSH. Overt hypothyroidism is considered an adverse effect and, if it occurs in a pregnant woman or infant, may affect the developing brain. Hypothyroidism is defined as sustained elevated TSH and low fT4. The NRC recognized hypothyroidism as the first adverse effect on the dose-response continuum (NRC, 2005).

2.2.1 There is no reference range for fT4

Although there is a reference range for TSH levels in different stages of pregnancy and in infancy, an analogous reference range does not exist for fT4. In the Final Peer Review Report of the model (Versar, 2017), it states,

ED_005043_00062727-00110

> Free T4 assays, as noted in the text, are poorly concordant with each other in pregnancy and some assays lose the expected inverse relationship with serum TSH values… It is generally recommended that normal thyroid function reference ranges be assay-specific, and that they should be defined in populations of individuals with no known history of thyroid disease, with adequate iodine intakes, and with negative thyroperoxidase (TPO antibodies).

The reason is that different laboratories have variations in techniques and populations that make direct comparisons impossible. Therefore, in general, a laboratory will consider a cutoff for "low" or "high" based on the percentile in the batch it is testing. This cutoff is commonly the lowest 2.5th percentile, 5th percentile, or 10th percentile. There is no recommendation by any authoritative medical body on the appropriate cutoff.

Although in the previous Peer Review of the model EPA chose to define provisional reference ranges for fT4, in the current document, EPA avoids this issue by using the model to estimate changes in fT4 which are mathematically associated with neurodevelopmental outcomes in Approaches 1 and 3. However, in the population shift approach (Approach 2), EPA defines hypothyroxinemia as the lowest 10th percentile on the calculated distribution based on the 50th percentile output from the BBDR model. That value is 8.8, 8.78, and 8.63 pmol/L for weeks 12, 13, and 16, respectively. The concern here is that these cutoffs are not applicable to testing in the population and cannot be diagnosed or experimentally tested. This cannot be validated in any meaningful way.

2.2.2 Hypothyroxinemia is not an adverse effect

Transient hypothyroxinemia is not uncommon in pregnant women and severely premature infants (born at less than 28 weeks). In an individual, hypothyroxinemia is not considered adverse. The ATA, American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Pediatrics (AAP) do not recommend treatment for hypothyroxinemia. The Endocrine Society suggests best judgement by the treating physician, however, does not recommend treatment in third trimester women (Furnica *et al.*, 2015).

Hypothyroxinemia as an endpoint to measure the effects of an environmental contaminant is questionable, particularly in pregnancy. There is a necessary rise in TT4, but also increased binding due to TBG, HCG, and other serum proteins. This results in hypothyroxinemia, but no change in circulating T3 levels with T3 being the active hormone. It is hypothesized that hypothyroxinemia is an adaptive response by the body to maintain adequate hormone level (Furnica *et al.*, 2015).

2.2.3 Treatment for hypothyroxinemia has not been shown to impact neurodevelopment

There is no study we are aware of that reports that perchlorate exposure causes hypothyroxinemia. The Agency assumes that it does. The Agency must provide the scientific support to justify including the endpoint of hypothyroxinemia and its relationship to neurodevelopment. Using fT4 solely from output of a BBDR model to predict a disease that the ATA states in their guidelines is not to be treated is not scientifically defensible.

Interventional studies have reported that treatment of the mother with synthetic T4 does not improve outcome compared to untreated (Lazarus *et al.*, 2012; Casey *et al.*, 2017). Importantly, these studies evaluate hypothyroxinemia in the first trimester with outcomes at up to 8 years of age. This is the period of interest based on the BBDR model results.

The first Peer Review report supported this and stated

> Despite the observational data suggesting a link between early gestational maternal hypothyroxinemia and adverse child developmental outcomes, there are now two randomized

ED_005043_00062727-00111

clinical trials...which demonstrate no benefit of levothyroxine treatment for maternal hypothyroxinemia on child IQ. (It is worth noting that both of these trials were limited by relatively late initiation of therapy; at 13 weeks in CATS and at 17 weeks gestation in the Casey study.) Given both the lack of interventional data demonstrating treatment benefit, and the challenges of establishing maternal free T4 reference ranges and treatment targets, current clinical guidelines (including newly published updated guidelines from the American Thyroid Association…) largely recommend against levothyroxine treatment for isolated maternal hypothyroxinemia."

2.2.4 Recommendation

We recommend the Agency use the BBDR model to consider hypothyroidism as the adverse effect.

2.3 Neurodevelopmental Testing

Assessing the neurodevelopmental outcomes from chemical perturbations during neurodevelopment is an area of study that is divided into many sub-disciplines. The documents and approaches the Agency has released simplifies a very complex area of study. In EPA's documents there are two components to examine carefully: the time of testing during gestation and the type of neurodevelopmental test given to the offspring.

2.3.1 Maternal thyroid testing

Neurodevelopment, or the controlled process by which the nervous system develops, has the potential to be affected by maternal and paternal factors. Neurodevelopment begins to occur about two weeks after conception in humans and continues until birth and up to early adulthood (Figures 1 and 2). The timing of neurodevelopment is documented, thus giving rise to windows of vulnerability to environmental insult during development (Figure 1 and 2).

ED_005043_00062727-00112

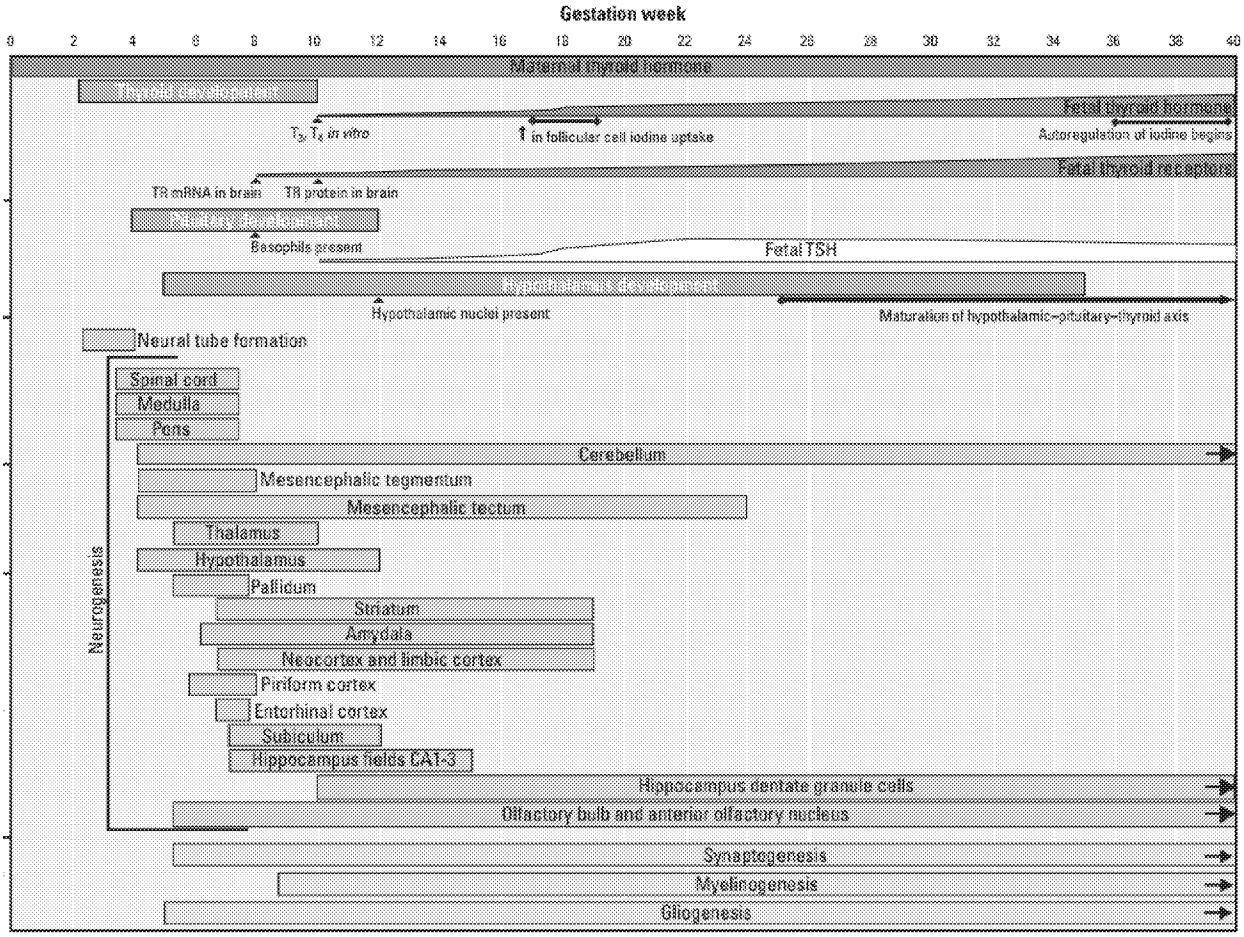

FIGURE 1 HUMAN *IN UTERO* THYROID AND NEURODEVELOPMENTAL TIMELINE
Timeline of human neurodevelopment. From Howdeshell (2002).

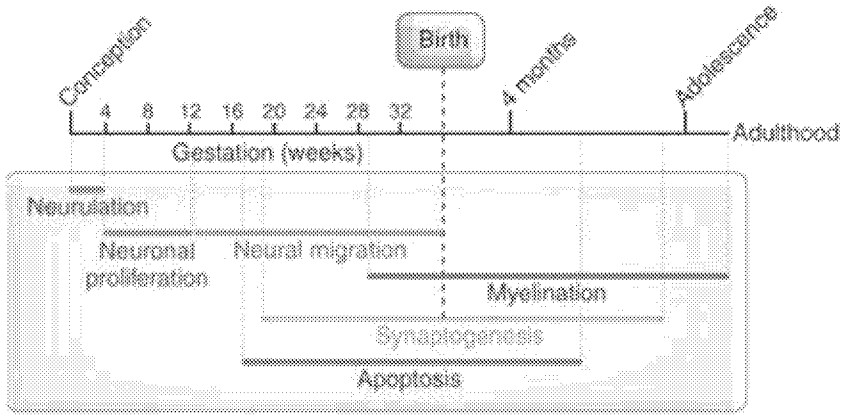

FIGURE 2 HUMAN NEURODEVELOPMENT FROM CONCEPTION TO ADULTHOOD
Timeline of major events in brain development from conception through adulthood. From Tau and Peterson (2010).

In the studies used by EPA, there is an attempt to quantify the association between a single measure of thyroid hormone in the first or second trimester with the neurodevelopment of her offspring over a year and up to 10 years after birth. During this period, there are many factors that could affect

development. There are other *in utero* conditions, exposures, maternal stressors, and nutrition that may contribute to variations. There are birth conditions, such as delivery complications, caesarian versus vaginal birth, or season of birth. There are post-natal conditions that may contribute. There is no way of knowing which of these things might affect neurodevelopment and to what extent. Statistically, factors that may affect both the variables and the outcome can be controlled for. However, in these studies, only a limited number of factors are considered, if any at all.

Severe iodine deficiency can cause neurodevelopmental effects via the reduction in thyroid hormones. However, the iodine status of the study populations used by EPA are not given except to say they are assumed to be iodine sufficient (Korevaar *et al.*, 2016; Pop *et al.*, 1999; Pop *et al.*, 2003; Finken *et al.*, 2013). Vermiglio *et al.* (2004) used a study population that is marginally iodine deficient and the control group is only marginally iodine sufficient. In Korevaar *et al.* (2016), the authors state,

> Another potential limitation of our study is the fact that we only had iodine data available from a small subset of 672 women (table), and iodine status could adversely affect both thyroid function and child brain development. Although this study was undertaken in a population with proven iodine sufficiency, we should note that iodine-deficient women, and those with high iodine intake, could still be present in the study population.

The Pop *et al.* (1999, 2003) studies did not measure iodide, but assume their population was sufficient based on previous studies. The authors state:

> Although 24-h iodine intake was not assessed either, previous population studies have reported sufficient iodine intake in the general population in this area, while other studies questioned whether this daily intake was sufficient for pregnant women with regard to the fetus.

EPA recognizes this weakness and writes:

> The data from all papers with the exception of Vermiglio *et al.* (2002; Italy) are from the Netherlands and are being considered for use in to inform the derivation of an MCLG for the United States. There is no reason to believe that the impact of fT4 on neurodevelopment would differ by country, unless there is a substantial difference in iodine intake. Unfortunately, exact data on iodine intake levels in the Pop *et al.* (1999, 2003) papers are not provided. However, the authors cite two studies on iodine levels in the general population of the Netherlands. Rees-Wortelboer *et al.* (1987) studied a sample of 253 Dutch women aged 23-32 and found a mean urinary iodide excretion (corrected for creatinine) of 115 μg/g creatinine. Brussaard *et al.* (1997) compiled studies on iodine supply after the introduction of iodized salt in the Netherlands in 1982. The researchers found that estimates of the mean iodine intake in women under the age of 65 ranged from 135 to 149 μg/day. An additional study of Dutch food consumption data from 1997-1998 by Verkaik-Kloosterman *et al.* (2010) estimated that the median iodine intake of adult women in the Netherlands was 204 μg/day. Iodine intake levels appear to be similar in the United States.

Other issues include measurements of clinical chemistry. An example is iron deficiency. A study in Swiss pregnant women reported that iron status predicts higher TSH and lower thyroid hormones (Zimmerman *et al.*, 2014). None of the neurodevelopmental studies control for or measure iron status.

2.3.2 Animal studies on neurodevelopment

EPA does not define neurodevelopment or what the neurodevelopmental tests are intended to document. Neurodevelopmental assessments require rigor and focus. The Agency is not clear on this and excludes key animal studies that provide useful information.

While the Agency suggests a process from perchlorate exposure to neurodevelopmental outcome, there is no science to support that health effects from perchlorate exposure progresses according to EPA's hypothesized MOA.

First, the NRC MOA of perchlorate is well understood and is not contested. Perchlorate affects the thyroid by competitively inhibiting iodide uptake to the thyroid through interaction with the sodium iodide symporter (NIS). This inhibition is reversible and not considered adverse. With sustained and significant inhibition—estimated to be about 70% inhibition for several months or more (NRC, 2005)—hypothyroidism could occur. Changes in thyroid hormone cannot occur without IUI; however, changes in thyroid hormones are not an inevitable consequence of IUI, that is, with cessation of exposure, no adverse health effects would occur.

Animal studies on perchlorate and neurodevelopment consistently report no significant changes in the developmental endpoints measured even with doses much greater than in human studies.

Second, there are several animal studies evaluating perchlorate exposure prior to and during pregnancy with a full battery of neurodevelopmental outcomes (Bekkedal *et al.*, 2000; York *et al.*, 2001; York *et al.*, 2004; York *et al.*, 2005). The endpoints reported for each study are summarized in Table 1. These were controlled animal experiments with doses ranging from 0 (controls) to 30 mg/kg-d (30,000 µg/kg-d or 1,050,000 ppb), dosed orally during gestation. These studies all report no significant changes in the developmental endpoints measured. This information is not presented in the EPA documents and we recommend it be included. Some of the neurodevelopmental tests include tests that scientist use to assess intelligence, motor, maturation and sensory outcomes.

The literature on untreated thyroid deficiency during pregnancy consistently demonstrates that hearing deficits are the most sensitive neurodevelopmental outcome. As noted below, no test of intelligence, motor, maturation, auditory startle, or other variable was shown to be different from controls at doses as high as 30 mg/kg-d.

ED_005043_00062727-00115

TABLE 1 ANIMAL STUDIES ON NEURODEVELOPMENT AND ENDPOINTS REPORTED

Study	Doses	Endpoint	Result
Bekkedal *et al.*, 2000	0, 0.1, 1.0, 3.0, 10 mg/kg-d	General locomotor activity	No significant change in general locomotor activity due to prenatal and neonatal perchlorate exposure
York *et al.*, 2001	0, 0.3, 3.0, 30 mg/kg-d	F1 generation brain weights	No significant changes in developmental parameters were observed
York *et al.*, 2004	0, 0.1, 1.0, 3.0, 10 mg/kg-d	Juvenile brain weights, morphometry, and neuropathology (PND 12); Adult regional brain weights (PND 89), morphometry, and neuropathology; Passive avoidance and water maze testing, motor activity and auditory startle habituation	No effect on body weights, feed consumption, clinical observations, or sexual maturation of pups; No neurodevelopmental effects as evaluated by passive avoidance, swimming water maze, motor activity, and auditory startle; Significant decrease in follicular lumen diameter at ≥1 mg/kg-d (males)
York *et al.*, 2005	0, 0.1, 1.0, 3.0, 10 mg/kg-d	Motor activity (PNDs 14, 18, and 22) and juvenile brain weights, neurohistopathological examinations, and regional brain morphometry (PNDs 10 and 22)	Authors conclude that the NOAEL for maternal toxicity was greater than 10 mg/kg-d and the NOAEL for pup toxicity was 0.1 mg/kg-d based on the thyroid morphometric and histopathologic findings

2.3.3 Human neurodevelopmental tests

The purpose of testing is to identify individuals who require specialized care and learning due to a developmental delay or disability. The validation group may be a group at a specific age from a specific country that may not correspond to the current US population.

In documents provided, the Agency is using four different tests of "neurodevelopment"; they do not measure the same endpoint. The tests used as a metric in these studies include intelligence quotient (IQ), psychomotor development index (PDI), motor development index (MDI), and the standard deviation of reflex time. A summary of these tests, what they measure, and the age to be tested, along with other characteristics is presented in Table 2.

There are fundamental issues to be addressed with using human neurodevelopmental tests that include the reliability, the variability, the test population, and the age the test was administered.

ED_005043_00062727-00116

TABLE 2 NEURODEVELOPMENTAL TESTS IN THE STUDIES USED BY EPA

Test	Description	Intended Age	Reliability	Variability
Snijders-Oomen Niet-Verbale Intelligentie Test IQ (test used in Korevaar *et al.*, 2016)	Subtests: Mosaics, which assesses spatial visualization abilities, and Categories, which assesses abstract reasoning abilities	2.5-7 median age of 6·0 years (95% range 5·6–7·9 years)	The mean reliability of the subtests of the SON-R 2.5-7 is 0.72 and the reliability of the total IQ score is 0.90. (wiki)	Median of 100, no SD found
Wechsler Intelligence Scale for Children, 3rd edition (WISC-III) (test used in Vermiglio *et al.*, 2004)	Verbal skills and performances in the following areas: general information, general comprehension, arithmetic, similarities, vocabulary, digit span, picture completion, picture arrangement, block design, object assembly, coding, and mazes	6-16	Subtest reliabilities (expressed as internal consistencies for all but the speeded subtest of Symbol Search and Coding) are moderate to excellent (.61 to .92). The consistency of IQS and Indices is very good to excellent (.80 to .97). Subtest stability coefficients, based on 353 children subdivided into three age groups, are adequate (.56 to .89). IQ and Index stability is mostly good to excellent (.74 to .95; only one coefficient below .80). Interrater reliabilities for selected Verbal Scale subtest are excellent (all greater than .92). (http://cps.nova.edu/ ~cpphelp/WISC-3.html)	For index and FSIQ scores, M = 100 and SD = 15
Bayley Scales of Infant Development PDI (used in Pop *et al.*, 1999, Pop *et al.*, 2003	Gross motor development	1-42 months 10 month olds (99) 1 year olds (03) 2 year olds (03)	Psychosocial factors, demographic features, life-style habits during pregnancy (smoking, alcohol), breastfeeding and the occurrence of stressful life events.	Mean of 100 and a standard deviation of 16 (Pop *et al.* state "these are still considered reliable")

ED_005043_00062727-00117

Test	Description	Intended Age	Reliability	Variability
Bayley Scales of Infant Development MDI (used in Pop *et al.*, 1999 Pop *et al.*, 2003)	Functioning such as hand-eye coordination, manipulation, understanding of object relations, imitation, and early language development.	1-42 months 10 month olds (99) 1 year olds (03) 2 year olds (03)	Scale composite average reliability coefficients ranged from .91 (Cognitive) to .93 (Language), whereas subtest average reliability coefficients ranged from .86 (Fine Motor subtest) to .91 (Expressive Communication and Gross Motor subtests). Within specific subtests, the lowest reliability coefficients (e.g., .71) were obtained in the younger age groups (e.g., 1-5 months) within the Receptive and Expressive Communication subtests. The average reliability coefficients for the special groups included in the sample were all greater than .94.	No information found
Amsterdam Neuropsychological Tasks (ANT) SD of reaction time (used in Finken *et al.*, 2013)	Attention, information processing, executive function, and visuospatial perception	3-47; The four parts of the test given are for use in ages 4+ subjects were 5.7 +/- 0.5 years	No information found.	Units are ms; a one unit drop is unclear as an adverse event

ED_005043_00062727-00118

2.3.3.1 Isolated test results are questionable

The results of a single test were never intended to be used to define the effect of small changes in thyroid hormones. Along these lines, it is difficult to portray what level of predicted change is adverse either to the individual or the population. EPA treats a one point change in the various metrics as significant; however, one point on the PDI is different than one point on the standard deviation of reaction time. EPA states:

> …considering the analysis for Finken *et al.* (2013), it is difficult to ascertain the true implications of a change in the standard deviation of reaction time, the endpoint with which there is a significant association with maternal fT4 levels.

The tests were also not meant to be considered in isolation or for differentiating small changes between individuals. For example, in the handbook of the Snijders Ooomen test, it states that:

> …administration of the test will not take place in isolation, but within a framework of discussions with, and observation of child and parent(s), and of information from schools or family doctors. An intelligence test is also frequently administered in combination with other developmental tests."

Similarly,

> The Amsterdam Neuropsychological Tasks Program (ANT) is intended for systematic evaluation of attention and information processing, ie. the basic conditions for the implementation of complex cognitive processes (including sustained, focused and divided attention, key aspects of executive function - such as attention-based flexibility, inhibition and work memory - simple and complex visual motor coordination, recognition of faces and emotions in the face and in the voice, frustration tolerance)."
> http://www.antprogram.nl/index.php

Thus, these tests must be administered with care by seasoned psychologists. Regarding use as toxicological endpoints, in a 1999 Society of Toxicology workshop (Bellinger, 1995) focusing on the use of neurodevelopmental testing in toxicological research, the participants concluded:

> In human neuropsychological work, many of the most commonly used tests were developed in the context of clinical evaluation, where the primary goal is to identify clinically significant impairments among patient groups (e.g., individuals with CNS insults such as traumatic brain injury, stroke, tumors, infections, etc.). Many domain-specific tests were not designed to detect small differences in performance within the normal range. In this respect, apical tests, which were developed to permit inferences about individual differences along the entire spectrum of performance, may be better suited than domain-specific tests to the task of detecting subtle impacts of toxicant exposures on neuropsychological function (Bellinger, 1995).

2.3.3.2 Tests are not predictive of adult intelligence

The Agency is evaluating whether exposure to a pregnant woman will cause adverse effects in her offspring. When tests are given to young children, the tests are not predictive of adult intelligence. Thus, these tests are not indicative of any long-term deficits. The study by Pop *et al.* (2003) accurately notes:

> …assessment of infant development at an early age still has only a limited value regarding the prediction of a child's abilities once it has reached school age. This is especially true of

> Bayley scores at 1 year of age, while at 2 years of age, these scores are related to functioning at 5 years of age.

And,

> In one study, we found a relationship between impaired infant development at 10–12 months and maternal hypothyroxinaemia during early gestation, but infant development at this early age still has only a limited value regarding the prediction of a child's abilities at later age.

2.3.3.3 Confounders are not adequately controlled

Clear confounders that must be controlled for very carefully are parental interaction quality and quantity, socio-economic status (SES), and education. Hart and Risley (1995), in their groundbreaking study, demonstrate that early language learning is a better measure of cognitive ability than any other measure. They conclused that the acquisition of language is the best measure of cognitive development as it can be accurately measured, and that a family environment with frequent and deliberate interaction with children is critical to neurodevelopment. When analyzing their dataset, Hart and Risley determined that SES was highly correlated with a child's language development.

Rigorous analysis of other confounders is necessary to assess the reliability of the study. One report noted:

> There is evidence that education has the greatest impact on performance in the cognitive tests used in neurotoxicity research (Anger *et al.*, 1997)… Clearly, educational background has a large impact on the cognitive tests used in this field, as does age, and to a lesser extent, gender (Anger *et al.*, 1997). Thus, cognitive research in human populations must control these factors in the groups under study, not in the analysis.

The use of studies without well-controlled study designs, limits the conclusions that can be derived and limits their use in regulatory decision making.

2.3.3.4 Clinical significance is unclear

Small changes between groups or even individuals are not likely to be meaningful or even persistent. For example, in testing two toddlers at age two where one has an IQ of 100 and the other has an IQ of 96, several observations can be made: 1) this difference is not a clinically-significant difference, 2) the ability of most behavior testing to predict future intelligence is poor, and 3) testing a two-year-old at the start of their language development is not meaningful and can be affected for numerous reasons.

If a variable, such as IQ, has a standard deviation of 15 points, a difference of 4 points is within the natural background variability. EPA has not provided a scientific rationale to support that differences within the inherent variability of the measure are meaningful.

2.3.3.5 The EPA uses studies with populations different than those in the US

One of the main concerns with the use of EPA's studies is their applicability to the US population. The US is iodine sufficient. There may also be significant demographic, ethnic, nutritional, and genetic differences between the study population and the population these data are applied to. The true differences cannot be known.

In particular, the study by Vermiglio *et al.* (2004) used a small population that was not randomly selected. The data were collected over a ten year period and included both moderately iodine

ED_005043_00062727-00120

deficient and moderately iodine sufficient age-matched mothers. The children in the study were also unusual in that there was a high incidence of goiter and ADHD (the focus of the study) among the subjects. At the time of conception, almost 25% of school-aged children in the moderately iodine deficient area had goiter. The intelligence test in this study was not given as a primary outcome measure to assess hypothyroxinemia, but as a secondary evaluation to rule out mental retardation. Eleven out of the 16 subjects in the moderately iodine deficient are were diagnosed with ADHD.

There may be other variables in thyroid status that suggest these populations are not applicable to the US population. When compared to a US population (Mortensen *et al.*, 2016), the TSH concentrations are similar in these populations, but the fT4 concentrations are lower in the Finken *et al.* (2013) and two Pop *et al.* (1999, 2003) studies (Table 3). The fT4 levels are similar to those in the Korevaar *et al.* (2016) and Vermiglio *et al.* (2004) studies.

TABLE 3 MEASURES OF FT4 AND TSH IN STUDY POPULATIONS

Study	Location	Date Collected	N	fT4 concentration (pmol/L)	TSH concentration (mU/L)	blood collection timing
Korevaar *et al.*, 2016	Rotterdam, Netherlands	2002-2006	3839	**14.9 (10.2–22.4)** median (95% range)	**1.35 (0.05-4.96)**	13·2 weeks (95% range 9·8–17·5)
Finken *et al.*, 2013	Amsterdam, Netherlands	2003-2004	1765	**9.6 (8.8 –10.4)** mean (SD)	**1.2 (0.8-1.7)** mean (SD)	12.9 w (median 90 d IQR 83-100)
Pop *et al.*, 1999	Veldhoven, Netherlands	1994	220	**13.1 (2.6)** mean (SD)	**0.14–2.2** Reference range for study	12 weeks (no range)
Pop *et al.*, 2003	Eindhoven, Netherlands	1997-1998	235	**12.1 (15.4–19.0)** mean (90% range); first group; mean not given for whole cohort	**0.15–2** Reference range for study	12 weeks (no range)
Vermiglio *et al.*, 2004	Sicily, Italy	1990-1992	27	**14.4 (1.7)** mean (SD)	**0.4–4.0** Reference range for study	Week 20
Mortensen *et al.*, 2016	United States	2009-2010	359	**14.3 (13.9, 14.5)** Arith mean (95% CI)	**1.46 (1.37-1.56)** Geo mean (95% CI)	Third trimester
ATA Reference Range				**13.9-23.4 (week 14) 11.1-19.7 (week 20)**	**<4.0**	

The ATA also notes there are differences in Dutch populations from US populations in stating:

> Initial studies of pregnant women in the United States and Europe first led to recommendations for a TSH upper reference limit of 2.5 mU/L in the first trimester and 3.0 mU/ L in the second and third trimesters. However, more recent studies in pregnant women in Asia, India, and the Netherlands, have demonstrated only a modest reduction in the upper reference limit.

This suggests that women in the Netherlands may have different ranges of thyroid hormones which would affect the slope of any regression based on data from these populations. Even if it were acceptable to use thyroid tests to predict decrements in neurodevelopment, it is not clear that these

populations would be appropriate for prediction in US populations based on either thyroid hormone measures or neurodevelopmental testing.

2.3.4 Recommendation

The literature supporting the association between hypothyroxinemia and adverse neurodevelopmental outcomes is equivocal at best, and lacks predictive power as the basis of a regulation. Consistent with the established perchlorate MOA and the weight of scientific evidence, the Agency should consider neurodevelopmental effects as downstream from hypothyroidism.

3.0 THE THREE APPROACHES

Two approaches are detailed in the main document. However, we note that a third approach is presented in detail in Appendix C. The third approach is scientifically weaker than Approach 1. We do not believe an approach confined to the Appendices should be used by EPA; however, we consider it here on the off chance that it is intended to be a serious approach.

> Approach 1: The BBDR model is used to estimate maternal fT4 levels with different intake levels of iodine and perchlorate. A change in fT4 is used to predict neurodevelopmental deficits in offspring based on a subset of epidemiological studies.
>
> Approach 2: The BBDR model is used to predict a population shift comparing the number of women who would be considered hypothyroxinemic under two scenarios.
>
> Approach 3: The results of a single study are used to predict a relationship between perchlorate and maternal fT4. A change in fT4 is used to predict neurodevelopmental deficits in offspring based on only one epidemiological study.

3.1 Approach 1: BBDR + Neurodevelopment

Approach 1 uses a two-stage approach: 1) BBDR to estimate changes in maternal fT4, followed by 2) the use of a subset of epidemiological studies to link maternal thyroid hormone levels to neurodevelopmental outcomes in offspring.

This approach depends on the use of realistic inputs and the ability of the BBDR model to accurately predict fT4 levels, and the use of a set of epidemiological studies selected through a systematic literature review.

3.1.1 Hypothyroxinemia studies that were used

One of the main criticisms during EPA's first Peer Review was the lack of transparency in the literature review. This documentation on the literature review for hypothyroxinemia studies is a great improvement. It was a targeted literature review as EPA reports:

> Based on the recommendations of previous peer review panels, EPA assumed that changes in thyroid hormone levels would be expected to lead to neurodevelopmental outcomes. For this reason, EPA did not conduct a complete, systematic review of the body of literature on this topic.

EPA documents its three step approach that resulted in fifteen Group 1 studies; these studies were chosen because they had continuous data and measured first trimester fT4. However, the final five studies selected for use in EPA's assessment were only those that had the association that EPA was seeking (positive association between fT4 and IQ). EPA states,

ED_005043_00062727-00122

That is, studies were identified that found an association between a continuous measure of fT4 and neurodevelopment and had all the requisite data to perform additional analysis to potentially inform the derivation of an MCLG.

Aspects of the final five studies have been discussed in sections 2.2 above. Based on EPA's own inclusion/exclusion criteria, several of EPA's studies are misclassified:

- Vermiglio *et al.* (2004): The regression presented in this study, and used by EPA, is based on week 20 thyroid hormone measures. This study should have been classified as Group 3 based on the incorrect measurement period.
- Gyllenberg *et al.* (2016): This study presents odds ratios that cannot be used as continuous data. It should have been classified as Group 2 based on the presentation of results.
- Heinrichs *et al.* (2010): This study presents odds ratios that cannot be used as continuous data. It should have been classified as Group 2 based on the presentation of results.
- Velasco *et al.* (2009): This study presents thyroid hormone data collected in the third trimester. This study should have been classified as Group 3 based on the incorrect measurement period.

3.1.2 Hypothyroxinemia studies that were not used

EPA ignored the weight of evidence in favor of using studies that only showed a positive relationship.

The remainder of the Group 1 studies generally do not report an association between maternal hypothyroxinemia and adverse neurodevelopmental outcome. When evaluated by time of serum collection, it is clear that EPA only chose studies that demonstrated a positive association (Table 4). Although there are more studies that demonstrate that no significant relationship exists, these studies were disregarded.

TABLE 4 POSITIVE AND NEGATIVE GROUP 1 STUDIES BY SAMPLE COLLECTION

	First Trimester (weeks 0-13)	Second Trimester (weeks 14-26)	Third Trimester (weeks 27-40)
Positive Studies	**Finken *et al.* (2013)** **Korevaar *et al.* (2016)** **Pop *et al.* (1999)** **Pop *et al.* (2003)**	None	None
Negative Studies	Moleti *et al.* (2016) Noten *et al.* (2015) Oken *et al.* (2009)	Chervier *et al.* (2011) Ghassabian *et al.* (2014b) Modesto *et al.* (2015) Román *et al.* (2013)	None

Studies by Gyllenberg, Heinrichs, Vermiglio, and Velasco have been removed as discussed in Section 3.1.1
BOLD studies were used by EPA in its analysis.

As discussed in section 2.2, neurodevelopmental testing has greater predictive power if given later in childhood. If we further categorize these remaining 11 studies by when the neurodevelopmental tests were conducted, we see that the negative studies overwhelmingly were given in later childhood years compared to the positive studies (Table 5). Taken together, it appears that EPA ignored the weight of evidence in favor of using studies that only showed a positive relationship.

ED_005043_00062727-00123

TABLE 5 POSITIVE AND NEGATIVE GROUP 1 STUDIES BY TESTING AGE

	Birth to <1 year old	1 to <5 years old	5-12 years old
Positive Studies	**Pop *et al.* (1999)**	**Pop *et al.* (2003)**	**Finken *et al.* (2013)** **Korevaar *et al.* (2016)**
Negative Studies	Oken *et al.* (2009)	None	Moleti *et al.* (2016) Noten *et al.* (2015) Chervier *et al.* (2011) Ghassabian *et al.* (2014b) Modesto *et al.* (2015) Román *et al.* (2013)

Studies by Gyllenberg, Heinrichs, Vermiglio, and Velasco have been removed as discussed in Section 3.1.1
BOLD studies were used by EPA in its analysis.

3.1.3 fT4 testing

Measures for fT4 are generally conducted in serum and since the 1970s, technological advances in radioimmunoassay (RIA), immunometric assay (IMA), and liquid chromatography-tandem mass spectrometry (LC-MS/MS) have continued to improve the sensitivity, reproducibility, detection levels, and incidence of errors. There are significant differences between test manufacturer protocols which may be in excess of the biological variation in fT4 levels (Spencer, 2017). Measures for fT4 are generally conducted in serum. Currently, serum-based immunoassays and LC-MS/MS techniques are available for measuring total and free thyroid hormones.

Tests for fT4 are generally used for screening followed by TSH screening or after TSH screening to confirm a diagnosis. Taken alone, the tests are less reliable. Even most current tests underestimate true fT4 values (Figure 3). An evaluation of current fT4 immunoassays shows significant between-method variability and tend to bias lower than the reference measurement procedure (RMP; equilibrium dialysis-dilution-mass spectrometry; Spencer, 2017)

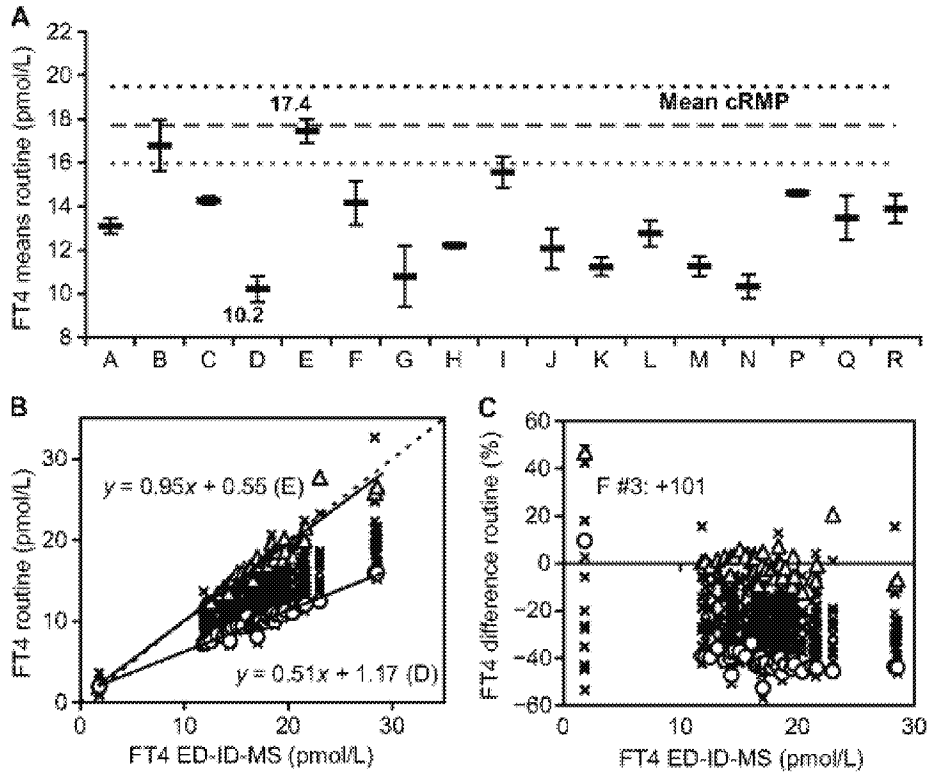

FIGURE 3 BETWEEN ASSAY COMPARISON OF FT4 MEASURES IN HEALTHY EUTHYROID SUBJECTS
Between Assay Comparison of FT4 Measurements in Healthy Euthyroid Subjects. A=FT4 assay means versus the mean by the reference measurement procedure (RMP; equilibrium dialysis-dilution-mass spectrometry). Different assays are coded A-O on the x axis. The dotted lines represent mean +/- 10% of the RMP ED-ID-MS). B=FT4 scatter plot (x=mean of the RMP vs. y= mean of 6 singlicate results per assay. Line of equality indicated by dotted line. The results for the most deviating assays are indicated by circles and triangles; all other assays are indicated with the same symbol, X. C=FT4 percent-difference plot indicating the strongest negatively (circles) and positively (triangles) biased assays. From Spencer (2017).

The type and brand of fT4 assay used in the five studies that were the focus of EPA's assessment are listed in Table 6. All five use different test packages and direct comparison is not recommended. It is not clear that a parallel relationship would persist between two different tests as there may be differences in sensitivity at high or low regions of the reference range. Therefore, statistical associations that presume that changes in fT4 would be consistent are unsupported by the analytical capabilities of the underlying tests.

Additionally, there are distinct differences in local populations that led the American Thyroid Association (ATA) to recommend population based reference ranges for pregnant women. The most recent ATA guidelines state:

> When possible, population-based trimester-specific reference ranges for serum TSH should be defined through assessment of local population data representative of a health care provider's practice. Reference range determinations should only include pregnant women with no known thyroid disease, optimal iodine intake, and negative TPOAb status.

TABLE 6 TYPES OF FT4 TEST USED IN THE FIVE STUDIES USED BY EPA

Study	Type of fT4 Assay	Brand	Detection Limit	Interassay Coefficient
Pop *et al.*, 1999	Chemiluminescence	Kodak Amerlite MAB FT4 Assay	8.7 pmol/L	11.1-12.2%
Pop *et al.*, 2003	Chemiluminescence	IMMULITE Free T4	Not given	5.2-20%
Vermiglio *et al.*, 2004	Radioimmunoassay	Amerlex-MAB	Not given	<5%
Finken *et al.*, 2013	Chemiluminescence	Beckman Coulter Access immunoanalyzer	1.9 pmol/L	3.1-5.0%
Korevaar *et al.*, 2016	Chemiluminescence	Vitros ECI; Ortho Clinical Diagnostics	Not given	<5.4%

3.2 Approach 2: BBDR Model Used to Predict Population Shift

Approach 2 uses a population-based approach which estimates the shift in the population of hypothyroxinemic pregnant women that would theoretically result from perchlorate exposure. There is no connection to an adverse effect. Overall, this approach has no reasonable scientific justification.

First, hypothyroxinemia is not an adverse, treatable endpoint. As noted in Section 2.2.2, the ATA and ACOG do not recommend treatment of pregnant women with hypothyroxinemia as there is no demonstrated benefit to doing so.

Second, the choice to define increases in the numbers of hypothyroxinemic women of 1 and 5 % is arbitrary. Since this is not an adverse effect, it is unclear what these values would represent.

3.3 Approach 3: Single Epidemiological Study to Predict fT4 + Neurodevelopment

Approach 3 proposes a two-stage approach as in Approach 1, but uses the relationship presented in a single epidemiological study (Steinmaus *et al.*, 2016) rather than the BBDR model to predict fT4 changes and uses the epidemiological literature to associate hypothyroxinemia with neurodevelopment (uses only Korevaar *et al.* (2016) as the example).

3.3.1 Limitations of the Steinmaus et al. (2016) for use in this manner

The Steinmaus *et al.* (2016) study used a cohort of pregnant women in Southern California (San Diego area) that were part of the Project Baby's Breath Study (a smoking and second hand smoke study). Samples from these women were collected in 2000-2003 and have been in storage. Serum samples were analyzed for TT4, fT4, and TSH and spot urine samples were analyzed for iodine, perchlorate, nitrate, and thiocyanate. The authors reported an association between increasing $\log_{10}$ perchlorate and decreasing fT4 and TT4 and increasing TSH.

One conclusion of the study was stated as:

> Thus, each 10-fold increase in perchlorate was associated with a 0.70-µg/L decrease in T4 and a 0.053-µg/L decrease in fT4, and each 1% increase in perchlorate was associated with a 0.071% increase in TSH.

Although this study contributes to the literature, it is unclear why EPA chose to use this particular study to define the relationship between maternal perchlorate and fT4. There are several concerns with the study design that suggest that this is not the study EPA should use to predict any type of relationship.

ED_005043_00062727-00126

First, the study samples were not collected concurrently. The spot urine samples for perchlorate were collect at a median of 7 weeks of gestation. The serum samples for thyroid hormones were collected at 17 weeks. Perchlorate has a half-life of 6-8 hours. The half-life of fT4 is 5-7 days.

Second, EPA has been clear that its focus is on the first trimester as these are the data that they can link to the neurodevelopmental data. The thyroid hormone data in Steinmaus *et al.* (2016) were collected at a median of 17.1 weeks. This is the second trimester.

Third, one of the interesting results of the study was that the relationship was strongest in women with the highest iodide. One would expect the association would be strongest in low iodide women.

Finally, although the regression produced an intercept which shows the direction of the association (negative or positive) with a 95% confidence interval to demonstrate variability, there are no statistics provided to demonstrate the statistical significance of the regression.

3.3.2 Comparison to BBDR results

As EPA states, the results from Steinmaus give very different values that are not consistent with the BBDR; the dose response of perchlorate on fT4 is much steeper in the epidemiology study compared to the BBDR. EPA notes that the fT4 based on low iodide intake (75 μg/d) is most similar to the lower bound estimate using the equation from Steinmaus *et al.* (2016). The lower bound estimate is based on the upper 95% confidence interval. This is surprising because the urinary iodide levels in Steinmaus *et al.* (2016) were relatively high. The median urinary iodide level is 154.5 and the mean and standard deviation is 214.9 ± 247.3 μg/L. The maximum urinary concentration of iodide was 3,000 μg/L.

Second, this comparison to the lower limit estimate from Steinmaus *et al.* (2016) isn't a comparison to actual data; rather, this is the estimated curve based on the regression of the data.

As discussed earlier, the results of the BBDR model over-predict the effects of exposure to perchlorate based on comparison to several data sets. Approach 3 over-predicts health effect to a greater degree and is not a useful approach.

3.3.3 Equations for deriving change in IQ

EPA uses simple linear equations for calculating change in IQ given a change in fT4. These are based on taking the beta coefficient and the unit change to a change in fT4 (usually some dose of perchlorate compared to no perchlorate). An inherent issue in this methodology is that the perchlorate baseline has a potentially large impact on the overall change. Assuming an equation that calculates the dose of perchlorate that can be applied to result in a 1 point change in IQ, a higher assumed baseline perchlorate allows for a larger amount of perchlorate to be applied (Table 7). Thus, a lower assumed baseline perchlorate will skew the results to a lower final perchlorate concentration.

ED_005043_00062727-00127

TABLE 7 EFFECT OF BASELINE PERCHLORATE ON FINAL PERCHLORATE CONCENTRATION FOR A 1 POINT IQ CHANGE USING THE KOREVAAR MULTIVARIATE MODEL

Baseline perchlorate concentration in urine (µg/L)	Rationale for Baseline Concentration	Baseline perchlorate dose (corresponding to urine) (µg/kg-d)	Perchlorate concentration after exposure (µg/L)	Ratio of baseline to post Urinary Perchlorate (µg/L)	Predicted perchlorate dose after exposure (µg/kg-d)
0.92	At fT4 10th percentile for non-pregnant women of cba in NHANES 2007-12	0.022	147.66	160.5	3.6
3	Median from NHANES 2001-02 cited by Steinmaus	0.073	481.5	160.5	11.7
4.1	Equiv to 0.1 µg/kg-d	0.1	658.05	160.5	16.1
6.5	Median from Steinmaus *et al.* (2016) cohort	0.16	8456.5	1301	206.3
2.25	Mid-point for lowest quartile (<4.5 ug/L), Steinmaus *et al.* (2016)	0.055	3970.35	1764.6	96.8

3.3.4 Comparison to other literature

Most importantly, the results of Steinmaus *et al.* (2016) are in stark contradiction of the rest of the scientific literature evaluating the association between urinary perchlorate and thyroid hormones in pregnant women. Table 8 lists other studies that studied this association with summary data on each. Of these, only the study by Charatcharoenwitthaya *et al. (2014)* reports an association. The results in every other cohort report no association.

Clearly, Steinmaus *et al.* (2016) is contrary to the weight of evidence, uses data collected later than the period of interest during pregnancy, and has study design flaws that preclude its use (i.e., non-concurrent urine and blood sample collection and lack of statistical evaluation of significance).

TABLE 8 STUDIES OF MATERNAL URINARY PERCHLORATE AND SERUM THYROID HORMONES

Study	N	Sample Collection for fT4 (median)	Urinary Iodine (median)	Urinary Perchlorate (median)	Results
Steinmaus *et al.*, 2016	1,476	17.1 +/- 1.5 w 2nd trimester	154.5 sufficient	6.5	Stated association with TT4, fT4, and TSH with perchlorate
Charatcharoenwitthaya *et al.*, 2014	200	9.6 +/- 2 w (mean) 1st trimester	153.5 sufficient	1.9	fT4 and TSH significantly associated with perchlorate
Horton *et al.*, 2015	284	12 +/- 2.8 w 1st trimester	138.5 marginally deficient	2.57	No associations reported
Mortensen *et al.*, 2016 (NCS cohort)	329	3rd trimester	Not given	4.0	No associations reported
Mortensen *et al.*, 2016 (NHANES cohort)	533	1st, 2nd, and 3rd trimester	Not given	3.3	No associations reported
Pearce *et al.*, 2010 (Cardiff hypo-thy/thyrox cohort)	374	12.5 (12.8 +/- 1.6 given in Lazarus *et al.*, 2003)	98	2.1	No associations reported
Pearce *et al.*, 2010 (Cardiff euthyroid cohort)	480	12.8 +/- 1.6 1st and 2nd trimester	117	2.6	No associations reported
Pearce *et al.*, 2010 (Turin hypo-thy/thyrox cohort)	261	12.8 +/- 1.6 1st and 2nd trimester	55	5.04	No associations reported
Pearce *et al.*, 2010 (Turin euthyroid cohort)	526	12.8 +/- 1.6 1st and 2nd trimester	50	5.2	No associations reported
Pearce *et al.*, 2011 (LA cohort)	134	9.1 +/- 2 1st trimester	144	7.8	No associations reported
Pearce *et al.*, 2011 (Argentina cohort)	107	10.0 +/- 2 1st trimester	130	13.5	No associations reported
Pearce *et al.*, 2012	134	10.9 +/- 2.3 1st trimester	120 marginally deficient	4.1	No associations reported

4.0 OTHER ISSUES

In Chapter 8 of its Draft Report, EPA lists other endpoints that may have a connection with perchlorate. Largely, these are unfounded and not supported by the literature.

4.1 Heart Disease

EPA reports that hypothyroidism is associated with heart and vascular disease. The MOA for perchlorate notes that hypothyroidism is the first hypothesized adverse effect due to perchlorate exposure (NRC, 2005). Although this has never been demonstrated in humans, no alternative to the MOA has been supported by the literature. Cardiovascular disease is associated with hypothyroidism, but is further down the continuum of effects. It is not a more sensitive endpoint than the recognized adverse effect of hypothyroidism or the first measureable effect of IUI.

ED_005043_00062727-00129

4.2 Comparative Toxicogenomics Database

EPA cites the Comparative Toxciogenomics Database as suggestive of "455 diseases potentially associated with perchlorate" and "mechanistic correlations have been reported for perchlorate exposure and thyroid diseases such as goiter and hypothyroidism, as well as necrosis, hypertrophy, and jaw abnormalities". EPA further states "Adverse health outcomes based on these alterations range from neurodegenerative disease to cancer."

The CTD is a large, hand-curated, integrative database with information on gene regulation, chemical exposures, and disease processes. It deliberately includes data from many different species, exposure protocols, and analytical techniques as it is intended to drive hypotheses. A study may report a gene up- or down-regulated in response to perchlorate (in any organism and at any dose). This gene may also be associated with disease processes or biological pathways that have not been reported to occur with perchlorate, but are associated with the gene change.

When querying "perchlorate," there are 158 genes changes, the two most common being SLC5A5 (the gene coding for the NIS protein) and TSHB (the gene coding for the TSH beta protein). Further, there are 487 diseases and 72 pathways. These diseases and pathways have largely not been demonstrated with perchlorate and are theoretical.

The studies the gene regulation are based on are not relevant to human exposures (e.g., high doses, animal models, exposure routes) and have inconsistent results (e.g., TSH both up and down regulated). Any disease or pathway associated with those genes are used to make the association. The CTD's intended use is viewing these relationships and forming hypotheses; then, the researcher can design studies to test these hypotheses. However, EPA's use of the CTD in a regulatory document is inappropriate and misleading.

5.0 OTHER GOITROGENS

Other chemicals have the same MOA as perchlorate and are found at levels in the diet that are greater than perchlorate, namely nitrate and thiocyanate. Cumulative risk assessment is commonly used by EPA when evaluating pesticides, but has not been applied under the SDWA. The total effect on IUI can be estimated using perchlorate equivalence. The equivalence is based on affinity of the anion to the symporter. The study to determine equivalence has been conducted in cell culture using human NIS transfected into the cells (Tonacchera *et al.*, 2004). This is a reliable method that has been used for decades in medical pharmacology. Although some criticize cell culture as a substitute for human studies generally, in this case, the relative interaction between the anion and the receptor is better quantified *in vitro*. Additionally, multiple animal studies have reported similar potencies of the three goitrogens (Wyngaarden *et al.*, 1952; Wyngaarden *et al.*, 1953). Willemin and Lumen (2016) also published the development of a PBPK model to evaluate the dose-response of thiocyanate; thus, it is possible to increase the utility of the Model by introducing nitrate and thiocyanate.

OIG released a report in 2010 recommending and demonstrating use of cumulative risk assessment for perchlorate, nitrate, and thiocyanate. OIG also included iodine deficiency as a thyroid stressor. The report noted that perchlorate accounted for less than 1% of total goitrogen load on the thyroid and regulation of this chemical in isolation would produce no benefit to public health. Other studies have also reported the same contribution of perchlorate to total goitrogen load (Tarone *et al.*, 2010; Bruce *et al.*, 2013).

Relatedly, the studies used to calibrate the model did not consider background doses of goitrogens. Only two studies were used to calibrate infant perchlorate, TT4, and fT4: Cao *et al.* (2010) and Leung *et al.* (2012). Cao *et al.* (2010) measured infant urinary nitrate, thiocyanate, and perchlorate, and reported geometric means and 95% confidence intervals for urinary nitrate of 95 μg/g creatinine (69-131) and urinary thiocyanate of 1000 μg/g creatinine (760-1320). In Leung *et al.* (2012), perchlorate, thiocyanate, and iodine were measured. For thiocyanate, they report thiocyanate levels of 373.5 μg/L (31.1–2420 μg/L) in maternal urine, and 193 μg/L (21.7–1880 μg/L) in infant urine (Leung *et al.*, 2012). The range that these two studies report spans two orders of magnitude suggesting significant variability in this study population. As a point of reference, NHANES 2011-2012 reports a geometric mean urinary thiocyanate and 95% confidence interval of 1133.5 μg/L (1002.1–1282.2) for females age 20 and older (Jain, 2016).

EPA does not include the other goitrogens in the model. Rather the Agency assumes that exposures are accounted for in the calibration populations.

> Since data used in the calibration of the BBDR model were taken from NHANES 2007-12, with exclusion only for frank thyroid disease or medical treatment, they are presumed to be representative of the U.S. population as a whole. Since the NHANES data are also used to estimate overall exposure of the U.S. population to other goitrogens, the degree to which these may not reflect actual population exposure would point to an underlying problem in the NHANES sampling. The use of these data in calibration of baseline thyroid hormone status effectively means that the predicted perchlorate dose-response is additive to the effect of existing exposure to other goitrogens in the NHANES 2007-12 population.

Thus, EPA's calibration based on studies where the impact of other chemicals with the same MOA also may be contributing to data reported is neither described as a limitation, nor considered in the assessment.

6.0 CONCLUSIONS

On September 15, 2017, EPA published a notice announcing the release of five documents, which taken together, provide the scientific basis to inform EPA's development of an MCLG.

We provided comments on the overarching topics of the revised BBDR model, hypothyroxinemia as an endpoint, and the derived association with neurodevelopment. We then discussed EPA's three approaches to inform the MCLG. Finally, we discussed other health endpoints that EPA mentions and the concurrent exposures to other goitrogens.

Regarding the overarching topics, we point out critical scientific issues.

BBDR model: EPA's revision has increased the ability of the model to accurately predict thyroid hormone in first trimester pregnant women, but the model continues to over-predict health effects for a given perchlorate exposure. To further the model for use in informing the MCLG, EPA should increase transparency, demonstrate validity with iodine deficiency in pregnancy, and provide a clear representation of limitations of the model. If EPA intends to use the output of the model to represent an average or median individual, the model parameters must also be chosen from the central point of the distribution. For example, modeling a weak TSH responder was a policy decision that results in a conservative output.

Hypothyroxinemia: Authoritative bodies such as the ATA and ACOG do not recommend treatment for hypothyroxinemia in pregnancy. The literature associating hypothyroxinemia and

ED_005043_00062727-00131

neurodevelopmental outcomes is not sufficiently robust to support a mathematical prediction. There is no study that reports that perchlorate causes hypothyroxinemia. There is no study that suggest that hypothyroxinemia is an intermediate step prior to hypothyroidism. EPA should consider using the accepted NRC MOA with hypothyroidism as the first adverse effect.

Neurodevelopment: The Agency is using multiple endpoints and those that are controversial from a scientific standpoint. The types of studies used are were developed to identify individuals who may require specialized learning programs due to clear disability. EPA focused on only five studies that were chosen because they reported a significant effect to the exclusion of all others. These five studies may not be applicable to the US populations and the associations are based on neurodevelopmental tests that lack sensitivity and specificity to detect small differences.

The three approaches are all limited by at least one of the above issues. Although we believe a revised BBDR model can inform the process, the use of hypothyroxinemia and neurodevelopment should not be used as EPA has proposed. The first two approaches use the BBDR model and either the epidemiological literature on neurodevelopment (Approach 1) or a theoretical population shift in hypothyroxinemic pregnant women (Approach 2). The second approach could be viable if the endpoint addressed were hypothyroidism rather than hypothyroxinemia, given the ATA's clinical position and the NRC MOA.

It is unclear if EPA intended the third approach to be a legitimate option as it is described only in the Appendix. Approach 3 proposes a two-stage approach as in Approach 1, but uses the relationship presented in a single epidemiological study (Steinmaus *et al.*, 2016) rather than the BBDR model to predict fT4 changes and uses the epidemiological literature to associate hypothyroxinemia with neurodevelopment (using only Korevaar *et al.* (2016) as an example). This study has critical flaws that preclude its use in the manner EPA proposes. The data from Steinmaus *et al.* (2016) overpredict fT4 levels to an even greater extent than the BBDR model. Approach 3 focuses on a single study to derive a correlation and disregards a large body of studies that shows no adverse health impacts at environmental levels of exposure.

In conclusion, we provided recommendations for the Agency that will improve the work they have conducted to this point in time. We appreciate the magnitude of work that EPA has conducted with the time constraints imposed by the Consent Decree to implement the improvements we see in the revised BBDR model. We believe that public health is best served with a rigorous scientific review. We appreciate that the Agency has such clear guidelines (*Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by the Environmental Protection Agency* (EPA, 2002)). We encourage the Agency and the Peer Reviewers to use this guidance as it provides a sound scientific approach to making important decisions on data quality for health assessments.

RE: PERCHLORATE PEER REVIEW

Dear Sir or Madame,

In response to the Federal Register Notice [EPA–HQ–OW–2016–0439; FRL–9967–70–OW] and on behalf of the Perchlorate Study Group (PSG),[1] Intertox is pleased to submit comments regarding EPA's *Draft Peer Review Charge Questions* on its *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water*. The EPA's charge questions can be found here.

We provide comments in this letter to the Agency. We outline overarching concerns with the document, we request that EPA provide essential documents to the peer reviewers, and we comment on the questions themselves. The Agency is releasing an updated BBDR model as well as three (not two) new proposed methods to derive an MCLG. It is an unrealistic expectation of the Agency to have volunteer experts provide input on important scientific issues without adequate time, transparency, guidance, and precise questions. We are concerned that the Agency will receive a peer review that lacks quality, consistency, and a viable path forward for EPA to improve. We submit these comments in the spirit of assisting and supporting the Agency in its mission to use the best science to determine an MCLG for perchlorate.

Overarching concerns with the Agency's document

There are four major issues related to the Peer Review process:

1) Inadequate time to review the documentation jeopardizes the quality of the peer review process
2) No clear process to critically review the updated BBDR model based on the criticisms of the first peer review panel
3) The manner in which the questions are written is inconsistent with the Agency's own Peer Review Handbook and cannot provide the quality of scientific information needed
4) Omission of questions on specific subjects casts the transparency of the process into doubt and must be addressed with additional questions

First, the Agency has set up a Herculean task for the peer reviewers: a critical review of more than 500 pages of dense scientific documentation by October 30, 2017 (45 days from when the draft report was published). With this timeframe the Agency places an undue burden on volunteer experts—they simply will not have the time to adequately digest the contents of this work given the

[1] *The Perchlorate Study Group is supported by Aerojet Rocketdyne, American Pacific Corporation, Lockheed Martin and Orbital-ATK. These companies have worked cooperatively with the U.S. Environmental Protection Agency to increase scientific and medical understanding of perchlorate's risk to human health.*

ED_005043_00062727-00139

multidisciplinary nature of the work the Agency is proposing. Therefore, the Agency reduces the strength of the peer review process and the scientific credibility it would impart.

Second, we are delighted that the Agency has listened to the first Peer Review and has updated its BBDR model on several critical issues. However, the BBDR model has changed significantly and thus needs a complete evaluation by scientists with experience, training, and knowledge and the ability to focus on the BBDR model rather than review the BBDR and all the additional material related to the MCLG approaches. Relatedly, the current EPA document fails to transparently discuss the criticisms of the first peer review panel. The Agency must make clear what the issues were rather than asking peer reviewers to read another technically dense document.

Third, the questions in EPA's document are not clear or precisely written. According to the Agency's handbook on peer review (4th edition of the Peer Review Handbook), there are two types of questions necessary for an adequate peer review. The first identifies broad scientific issues on which the Agency would like feedback. There are only two questions that EPA lists under "General Questions" for the reviewers to answer. The remainder are all highly technical, requiring expertise in PBPK modeling, maternal endocrinology, cognitive sciences, and epidemiology. All questions need to be rewritten for the Agency to obtain the quality of scientific information it seeks.

Fourth, there is a clear issue of transparency in the omission of questions on the third approach the Agency is proposing to derive an MCLG. Using Steinmaus *et al.* (2016) to derive the MCLG is an additional approach. The documents need to be rewritten to address this point. We provide specific examples of questions that address this topic below.

Documents EPA must provide to peer reviewers

The Agency must add additional resources to support peer reviewers with their tasks. The database of perchlorate literature is robust, replete with high-quality scientific studies conducted over 60 years. The Agency must provide the authoritative reviews by the National Research Council and ATSDR's Toxicology Profile for perchlorate. These documents will provide the reviewers with the foundational scientific information on the toxicology and pharmacology of perchlorate, which is essential to a rigorous evaluation of perchlorate.

Given the Agency's requirement for high quality information, peer reviewers should be directed to, and required to read, the Agency's *Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by the Environmental Protection Agency*.[2] It would help the peer reviewers to understand the importance of data quality, and how the Agency reviews its scientific information.

Comments on Specific Questions in the Document

General Questions

These need increased clarity. The Agency will not receive quality information when it asks peer reviewers to "comment on the appropriateness." The questions lack specificity, generally requesting the reviewers to "provide comments" rather than asking specific questions. There are many examples of these ambiguous phrases throughout the charge questions. Such undefined requirements for answering a question make it difficult for any peer reviewer to provide a consistent and thorough assessment. The Agency must provide clear and directed questions that are critical to understanding the goal and limitations in determining whether to set or not set an MCLG.

[2] https://www.epa.gov/sites/production/files/2015-08/documents/epa-info-quality-guidelines.pdf

Specifically, the questions need to be rewritten to be more directive in obtaining the information the Agency needs.

Additionally, more broad questions are required. We suggest additional general questions below to support the peer reviewers in providing constructive feedback to the Agency, taking into account the context, background science and possible limitations of what they are being asked to do.

1) Several human studies specifically evaluate a nonadverse and precursor event to thyroid hormone changes. The most conservative No Observable Effect Level (NOEL) for IUI is 7 μg/kg-d (Greer et al., 2002). Importantly, no other effects (i.e., changes in thyroid hormone) occur unless IUI occurs first. The BBDR model predicts changes in thyroid hormones without changes in IUI. How should EPA reconcile the clinical data with the BBDR results?

2) Given the inherent conservatism of the BBDR model output (fT4) to population shifts of hypothyroxinemia and possible cognitive changes, does the literature support this mechanism of action and the predicted effects (perchlorate exposures causing isolated maternal hypothyroxinemia leading to permanent cognitive changes in offspring)? EPA uses only five population studies that demonstrate cognitive outcomes. Is this scientifically defensible? Should negative studies and/or additional clinical be used in the assessment?

3) The EPA SAB in 2012 recommended that the Agency use hypothyroxinemia as an endpoint. The Agency is concerned that there were no clinicians on the panel to aid the Board in making that determination. Clinicians were requested to participate in the first peer review and stated that hypothyroxinemia is not a clinically defined or treatable disease, whereas hypothyroidism is. Is the Agency still required to use hypothyroxinemia rather than hypothyroidism, an adverse effect, as the endpoint of concern?

4) The updated BBDR model incorporates changes to its first released model. The Scientific protocol would require this model be peer reviewed again. Has the Agency provide sufficient time, resources, expertise, and evaluation of this revised model? What expertise in this peer review group is used to make this assessment? Did any of the peer reviewers have the time, equipment, and resources to build and run the model? Did any of the peer reviewers ask EPA to run scenarios for them? What is the clear recommendation of the peer review on how to use this model?

5) The Agency uses conservatism in its approach to determining acceptable exposures for the US population. The purpose is to err on the side of not underpredicting a possible health effect. To derive an MCLG for perchlorate, EPA is engaging new methods to set acceptable levels of chemicals, and each method is conservative. If using a BBDR model has built-in conservatism, the translation to fT4 to clinical significance is conservative, and the approach to determining cognitive effects is conservative, how accurate is this new method, and is it realistic in predicting adverse outcomes?

6) The Agency is interested in assessing neurodevelopmental effects of chemical agents. However, neurodevelopmental effects cover a broad range of effects from motor, cognitive, reaction time, behavioral, and many others. For this assessment, we are using several neurodevelopmental endpoints. Given that, are all neurodevelopmental endpoints relevant or are some more important than others? The tools used to test for these developmental parameters are rather specific to a certain age and population, so, is it appropriate to use any specific age group as the metric? If a tool is useful for a given age and inadequate for prediction of long-term effects should it be used? If there is a statistically significant effect

(e.g., IQ point difference of 2 points) and the standard error of the test is +/- 10 points, is this an important outcome?

The lack of broad questions raises a concern over transparency. It is not in the Agency's best interest to focus peer reviewers on a small portion of a robust database when the Agency needs a strong scientific rationale for deciding whether it should set an MCLG for perchlorate.

Technical and Specific Questions

As noted above, the amount of material to critically review and provide the Agency with comments on by October 6th cannot possibly be given adequate consideration or the required scientific vigor, . This is particularly the case for the technical questions. The lack of adequate time should give the Agency pause to ask itself if it is getting the quality it needs.

Parallel to our observations about the ambiguity of language for broad questions, the same improvement to issues in the technical section is needed. Peer reviewers need clear and concise questions so that they can help the Agency. As currently written, the technical questions allow the Agency to disregard the question if misinterpreted, for example. Unclearly written questions waste a valuable opportunity to obtain critical feedback that will be used to support EPA's final MCLG.

We are concerned about the lack of questions regarding the use of Steinmaus et al. (2016) to define the change in fT4 levels. Using Steinmaus et al. (2016) adds a third approach to calculating an MCLG. The lack of Charge Questions for this third approach is puzzling. We submit potential questions below for consideration and request that the Agency provide more questions to guide the peer reviewers on this approach. The scientific validity of this approach <u>must</u> be assessed.

1) In its 2013 report, the SAB found that the 13 epidemiological studies that had been published since 2005 were "*insufficient to guide causal inference with regard to the association between perchlorate exposure and thyroid dysfunction*."

   In Appendix B of its report, the SAB identified important limitations of these epidemiological studies. In Appendix C of the Peer Review Draft, EPA uses two epidemiological studies (Steinmaus et al. (2016) and Korevaar et al. (2016)) to create a quantitative estimate between perchlorate exposure and change in IQ.

   > Do the studies used in Appendix C have similar limitations in determining causal inference as the ones the SAB listed in Appendix B of the SAB report? Is EPA's use of the epidemiology studies in Appendix C consistent with the advice provided by the SAB?
   >
   > Do these two studies avoid the problems of confounding, other goitrogen exposure, and limitations of spot urine sampling the SAB identified in Appendix B of the SAB report?
   >
   > Is the use of these two studies in isolation and the absence of other studies (to gather the weight-of-evidence) scientifically defensible? Please list and comment on other studies would have been relevant.

2) The estimated thyroid hormone changes in Steinmaus (2016) differ from the results of the BBDR model by a substantial margin.

   Does the report adequately explain the reasons for the differences? If not, what are the scientifically-justified reasons? What are the potential confounders in Steinmaus et al. (2016)?

   Is EPA's use of the perchlorate concentration at the 10th percentile fT4 level justified as a baseline perchlorate concentration? What are other approaches for defining a quantitative value of "baseline?"

   The assumption of baseline perchlorate has a profound effect on change in fT4. Does EPA adequately justify the use of its value as opposed to a mid-distribution value or some other point on the distribution? Should this value by tied to fT4?

   Based on the weight-of-evidence, which approach (BBDR or results of Steinmaus et al. (2016)) is a better approximation of the U.S. population fT4 and sensitive sub-population fT4?

3) In Appendix C of the Peer Review Draft, EPA uses one of the five relationships used in the main report to relate the Steinmaus (2016) change in fT4 to changes in IQ.

   Please list and comment on the scientific merits and limitations of selecting the Korevaar (2016) study for this relationship.

   The study populations in the two studies (Steinmaus and Korevaar) are different (e.g., ethnically, socioeconomically, nutritionally). Did the analysis in Appendix C adequately control for these differences?

   The analysis conducts a partial Monte-Carlo analysis of variability of the two effect estimates. Does this approach fully characterize the uncertainty in the quantified estimates in Appendix C?

   Tables C-6 through C-8 show that at least a 13% reduction in fT4 is required to lead to a change in one IQ point. These results do not account for homeostasis and the TSH-moderated feedback loop that would increase the production of thyroid hormones as in the BBDR model. Please comment on the scientific basis of this approach.

Thank you for the opportunity to provide these comments. Intertox continues to read the EPA documents and will provide more specific comments to EPA as soon as it is able.

Sincerely,

Richard C. Pleus, PhD, MS

RE: PERCHLORATE PEER REVIEW

Dear Sir or Madame,

In response to the Federal Register Notice [82 FR 43362 (September 15, 2017)] and on behalf of the Perchlorate Study Group (PSG)[1], Intertox is pleased to submit comments regarding the Interim List of Peer Reviewers. The PSG is committed to assisting the Environmental Protection Agency (hereafter EPA or the Agency), as the PSG has for more than 16 years, to ensure that the information it disseminates adheres to the basic standards of quality, objectivity, utility, and integrity. It is in this spirit that Intertox provides comments on the interim list of peer reviewers.

The Agency has released an updated BBDR model as well as three (not two) new proposed approaches to derive an MCLG. It is unrealistic of the Agency to release more than 500 pages of technical documentation and expect to receive constructive comments on the main document and appendices, the updated BBDR model, comments on Charge Questions, and the Interim Peer Review Panel. The Agency has presented groundbreaking and highly influential science and it deserves thoughtful response.

Based on a review of the documents provided by EPA, additional disciplines are required which are not represented by the scientists listed on the Interim List. These must be included for a meaningful review:

- Developmental psychologists - experts in childhood development; expertise in instruments (e.g., IQ tests) to predict adult outcomes from studies in children
- Clinical psychologists - experts in the use and administration of cognitive testing
- Receptor pharmacologists - experts in the understanding of the physiology of receptors (e.g., endocrine receptors)
- Thyroid endocrinologists with expertise in neurodevelopment - expertise in endocrinology with a subspecialty in neurodevelopment
- Statistician in population studies - expertise in how to apply hormonal outcomes to populations

The first peer review benefited from having clinicians empaneled to address key issues of relevance and significance of thyroid hormone values and clinical outcomes. These issues will be just as key

[1] *The Perchlorate Study Group is supported by Aerojet Rocketdyne, American Pacific Corporation, Lockheed Martin, and Orbital-ATK. These companies have worked cooperatively with the U.S. Environmental Protection Agency to increase scientific and medical understanding of perchlorate's risk to human health.*

ED_005043_00062727-00145

for the present peer review process and the clinicians should be included in the second peer review. Furthermore, with the evaluation of the revised BBDR model, expertise in modeling is required in this second peer review; thus, the BBDR modelers should also be included.

Thank you.

Sincerely,

Richard C. Pleus, PhD
Intertox, Inc.

ED_005043_00062727-00146

The US Conference of Mayors

November 17, 2017

Mr. Michael H. Shapiro
Acting Assistant Administrator
Office of Water
US Environmental Protection Agency
Washington, DC

RE: Comments on EPA's Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate - Docket ID No. EPA-HQ-OW-2016-0438, (82 Fed. Reg. 43354, Sept. 15, 2017). http://www.regulations.gov

Dear Mr. Shapiro:
The United States Conference of Mayors (USCM) appreciates the opportunity to provide comments to the U.S. Environmental Protection Agency (EPA) regarding the "**Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate".** USCM has followed the development of this rule for a number of years because it impacts our member cities who provide drinking water in their communities.

The USCM commends EPA for developing the revised "Biologically Based Dose-Response (BBDR) Model"; and, development of several Approaches to Inform the Derivation of a Perchlorate MCLG". While these models are intended to derive a limit and a goal for perchlorate we are concerned about the multiplicity of model uncertainties, and the lack of replicated studies to support a limit. We request that EPA make fully transparent the magnitude of uncertainty these models present, and how the panel dealt with them in combination.

Local government is the primary provider of municipal drinking water in the United States, spending over $65 billion on services and infrastructure. Our citizens and customers are also facing water service affordability issues in every community. Any new primary drinking water standard will require rate increases, and thus we urge EPA to weigh the level of uncertainty in the models supporting the rulemaking against the cost of compliance.

USCM appreciates consideration of these comments by EPA and peer review panel. If you have any questions, please feel free to contact Rich Anderson (randerson@usmayors.org) or Judy Sheahan (jsheahan@usmayors.org) of my staff.

Sincerely,

Tom Cochran

Re: Docket ID No. EPA-HQ-OW-2016-0438-0017: Requests for Comments: Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate

Western Growers is a non-profit trade organization that represents California, Arizona, Colorado and New Mexico based growers and handlers of fresh fruits nuts and vegetables. Our members produce and sell over half of the total US fresh produce including both conventional and organic crops. Over the years Western Growers has provided commentary to USEPA and others regarding lower regulatory limits for perchlorate because of our concerns for potential adverse impacts to growers including increased water costs and perceptions about the safety of foods that may contain traces of perchlorate and other thyroid inhibiting compounds.

Western Growers appreciates the opportunity to provide brief comments on the BBDR documentation and model as USEPA strives to assure scientific rigor of the model development and validation. The decisions that are made by USEPA during this development period have a direct bearing on not only the water providers but also many water users including growers in the West.

Among our key concerns is the identification of the appropriate endpoint. Western Growers has long contended that transient thyroid hormone changes are not adverse in and of themselves. It is our understanding that hypothyroidism is the first adverse effect (NAS 2005) and that there are several non-adverse precursors to the first adverse effect, including inhibition of iodide uptake in the thyroid, which is the first measurable effect in the body. It seems that USEPA is contemplating the use of hypothyroxinemia, which is not an adverse effect, and Western Growers asks that the rationale for this decision and its departure from the National Academy be clearly articulated as USEPA moves forward.

If the MCLG is established on the basis of an effect that occurs upstream of the identified first adverse effect, and that effect is transient as well as heavily influenced by many factors other than simple exposure to perchlorate, it could set a problematic precedent for future regulatory decisions. The agricultural industry is certain to be impacted by the USEPAs decision making on perchlorate. Western Growers urges the USEPA to take a realistic approach to their modeling efforts beginning with the selection of appropriate critical effects.

Respectfully,

Senior Vice President
Western Growers

Springfield, VA 22151

I. INTRODUCTION

Versar, Inc. (Versar) is an EPA contractor charged with coordinating the external peer review of EPA's Draft Biologically Based Dose-Response (BBDR) model and a draft BBDR model report entitled "Biologically Based Dose-Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses." As part of the peer review process, EPA published a Federal Register Notice (81 FR 67350) on September 30, 2016 to announce a public comment period. The original 45-day public comment period ended on November 14, 2016, but the public comment period was extended until November 25, 2016. Supporting documentation, including the charge questions that will be addressed by the peer reviewers, was also made publicly available.

The purpose of this document is to provide a brief overview of the public comments submitted to EPA's public docket (Docket ID No. EPA-HQ-OW-2016-0438) by the published deadline of November 25, 2016. The public comments in their entirety are included with this report (Attachment 1) and are also available for download from the Federal docket (*http://www.regulations.gov*).

II. PUBLIC COMMENT OVERVIEW

A total of 10 comments/submissions on were uploaded to the docket, however, only nine of these submissions contained technical comments on the BBDR model and report, as one submission (from the Perchlorate Study Group) was a request for an extension to the public comment period.

The following nine organizations/individuals submitted technical comments:

- Department of Defense
- Izze Kraiman, West Chester University
- The Chlorine Institute
- American Chemistry Council
- American Water Works Association
- Environmental Defense Fund/Natural Resources Defense Council
- Intertox, Inc. (prepared for Perchlorate Study Group)
- Gradient
- NASA

Table 1 below provides a list the comments submitted, the number of pages for each, the technical author (if provided), and a list of topics covered. Overall, the comments discussed EPA's choice of hypothyroxynemia as the critical effect, the lack of data or limited data for model parameterization and validation, compensatory (homeostatic) control mechanisms, and chemicals with the same mechanism of action as perchlorate, among other topics. Some of the submitted comments pertain to the maximum contaminant level goal (MCLG), and therefore are not applicable to this peer review meeting. A second peer review will be held in the future on a report that evaluates methods to apply the final BBDR model to develop a MCLG for perchlorate in drinking water.

Public Comments Submitted to Docket EPA-HQ-OW-2016-0438				
Submitter Organization	Technical Author	No. of Pages	Topics covered	Notes
1. Department of Defense	Not provided	10	• HPT feedback system • Binding assumptions for thyroid hormones • Maternal fT4 during pregnancy and neurodevelopmental effects • Statistical definition of hypothyroxynemia and adverse outcomes at lifestages considered • Literature search for BBDR model • Clarification of data review process for model calibration • Discussion and documentation of model calibration process • Model calibration results and summary of calibration results • Dose-response evaluation • Local sensitivity analysis of BBDR model with perchlorate • Three-compartmental thyroid • 'Normal adult' urinary clearance parameter for lactating mother	Twenty specific comments with suggested actions organized by categories: 11 science comments classified as major, 8 science comments not classified as major, and 1 editorial comment.
2. Izze Kraiman, West Chester University	--	8	• Proposed maximum contaminant level (MCL)	Document discusses studies that support the proposed MCL of 0. 7 µg/day.
3. The Chlorine Institute	Not provided	4 + 31 page ENVIRON study	• Lack of data or limited data for the life-stage human values • Aggregate and cumulative exposures to chemicals with the same mode of action to perchlorate • Lack of appropriate data to validate the method • Homeostatic control mechanism • Additional resources to be reviewed and considered in proposed BBDR model	The commenter provided an evaluation conducted by ENVIRON International Corporation on the health advisories and standards for perchlorate levels in drinking water.

1	General	All	A major limitation on the use of these models is the lack of incorporation of the hypothalamic pituitary thyroid (HPT) axis in the models, this limits their ability to focus on the underlying mechanisms that are disrupted by perchlorate. Use of models that are restricted to operating at levels of perchlorate and iodine intake where thyroid homeostasis is expected to be auto-regulated ignores sensitive subpopulations, such as already hypothyroid pregnant women and fetuses. A robust model should predict kinetics and sometimes responses over a large range of doses; this can often help ensure that predictions are mechanistically based rather than simply empirical. Further the use of the model for other thyroid disruptors is restricted without the inclusion of the HPT axis.	There is available tracer data (both radioiodide and thyroid hormones), as well as existing thyroid hormone models (DiStefano et al., 1982; Eisenberg et al., 2010) in the literature that could be incorporated into the model structure. Please consider expanding the iodide model to include the HPT feedback system. This would expand the applicability of the model for addressing similar anions that exist at higher concentrations in the environment than perchlorate as well as future contaminants that may disrupt thyroid function. DiStefano JJ 3rd, Malone TK, Jang M. 1982. Comprehensive kinetics of thyroxine distribution and metabolism in blood and tissue pools of the rat from only six blood samples: dominance of large, slowly exchanging tissue pools. Endocrinology. 1982 111(1):108-17. Eisenberg M, Samuels M, DiStefano JJ III. 2008.	S/M

				Extensions, validation, and clinical applications of a feedback control system simulator of the hypothalamo-pituitary-thyroid axis. Thyroid 18:1071 - 1085.	
2	Model Structure	General	The model assumes nearly all of T4 and T3 are bound to serum proteins with a small fraction free and it assumes perchlorate does not bind to plasma proteins. There is evidence that an increase in serum fT4 follows the administration of perchlorate and other anions (Machajlovskij and Langer, 1974) and fT4 levels return to normal when the anions are cleared, suggesting the displacement of the hormones by perchlorate or similar anions.	Binding assumptions should be explored and compared to any available data. Machajlovskij and Langer, 1974. Increase of serum free thyroxine following the administration of thiocyanate and other anions in vivo and in vitro. Acta Endocrinol 75:707-716.	S/M
3	Executive Summary	7, lines 22-23	The executive summary states the following about model predictions: "however, the lactating mothers were predicted to become hypothyroxinemic or hypothyroid at perchlorate exposures below 20 µg/kg/d"..." The criterion to predict hypothyroidism, TSH increase, is not included within the scope of the model, so hypothyroidism cannot be predicted.	Remove "or hypothyroid".	E
4	Introduction	9, lines11-12	Evidence for a relationship between maternal hypothyroxinemia during pregnancy and neurodevelopmental effects in infants/children	Consider developing a dose-response relationship between maternal fT4 during pregnancy and risk of neurodevelopmental	S/M

			appears to be better supported by the literature than effects of neonatal (postnatal) hypothyroxinemia on development are.	effects from available data irrespective of known perchlorate exposure. While a correlation between maternal and fetal fT4 is clearly expected, why not take advantage of the empirical data documenting a relationship between maternal fT4 and neurodevelopmental outcomes? The existing pregnant mother model could be used to compute effects of perchlorate exposure on maternal fT4 during pregnancy. Such an approach circumvents the arbitrary and ambiguous nature of selecting a particular percentile of fT4 as adverse effect.	
5	Introduction	12, lines 1-2	The introduction of Fisher et al. (2016) does not provide support for sensitivity of infants. The SAB report suggests such sensitivity is plausible, but does not provide any evidence for an effect, much less greater sensitivity.	Please use wording that more accurately reflects the content of the cited references, or eliminate the statement.	S
6	Introduction	17	A statistical definition for hypothyroxinemia is provided without addressing adversity associated with the definition for each lifestage considered in the model (mother, fetus, infant). Low levels of fT4, without consideration of other thyroid indicators, are not clearly adverse, as acknowledged by EPA.	Please indicate whether their hypothyroxinemia definition is meant to indicate bounding conditions within which the model is expected to be "reliable" or whether hypothyroxinemia, as defined here, is an adverse outcome at each lifestage.	S/M
7	BBDR Model	23	The document indicates that the PubMed search	Please clarify how references were identified	S/M

	Development and Parameterization		conducted to identify relevant papers for this activity occurred in December, 2013, almost three years ago. It does indicate that other papers were "later identified as potentially relevant", but does not indicate the mechanism by which additional papers where identified or set a clear literature cut off date. One of the primary data sets used for calibration has a publication date beyond the 12/2013 date (Gordon et al., 2014, as noted on p. 24).	after December 2013. Was it done systematically? EPA should conduct their own, updated PubMed search and review and provide the results to the reviewers/stakeholders, rather than shifting the burden of additional data identification to the reviewers (e.g., per Draft Charge Questions 1B and 3).	
8	BBDR Model Development and Parameterization	23	The text states that "62 articles had data that were used for calibration, validation or setting model parameters. Information for these 62 specific articles are provided in ReviewHERO416.xlsx. The review process was halted after it was judged that the objective had been met; i.e., sufficient data for model calibration had been identified." The statement that the review process was "halted" when "sufficient data had been identified" is unclear and confusing. Were all 62 articles reviewed and used? How was a threshold for "sufficient" data identified? Would more data not have the potential to improve model confidence? What possible actions in the review process were not pursued because "sufficient data" had been	Please provide this spreadsheet and clarify its data review process.	S/M

			identified? These statements seem contrary to the spirit of systematic review.		
9	BBDR Model Development and Parameterization	27-29	The model calibration process is not discussed in any detail, other than to state within the tables that certain parameters were fit visually to specified data sets.	Please indicate whether visual fitting was conducted in a certain sequence, or whether it was refined iteratively. When multiple data sets were used for calibration of a given parameter, EPA should indicate how different studies were weighted. The document should also indicate why visual fitting was used rather than a formal optimization process and discuss the implications for model confidence and precision.	S
10	BBDR Model Development and Parameterization	27-29	A primary goal of the public review of the BBDR documentation and model is understood to be an assessment of the scientific rigor of the model development and calibration/validation process. As such, complete transparency regarding calibration of model parameters is expected. Tables 4 and 5 should clearly indicate which plots show the data to which the parameters were fit. Reference (by figure number) to plots in previously published papers would be acceptable when models have not been appreciably altered. All plots for optimizations for the current effort should be shown. For example, T3 data were reportedly used to optimize the parameter T3FRAC_N), but	Please add figures where necessary (or add them to an Appendix) to document the model calibration process and then reference those figures (and existing figures in prior publications) in Tables 4 and 5.	S/M

			no fits are shown.		
11	Model Calibration Results and Summary of Calibration Results	60-68	The calibration results are characterized as: "Overall, the model predictions were considered adequate" (page 60). No scale, frame of reference, or justification for its characterization of the predictions as "adequate" is provided. Later (pp 62-8), the phraseology "within the range" of reported values is used repeatedly. At a minimum, the model should be judged on comparison to the central tendency of reliable data. While it is stated that "model predictions should roughly match average values in each data set", they frequently do not (e.g., Figure 5, Figure 7 upper panel). The criterion is justified as being "within the range" (a relatively low bar for model agreement) on the basis that only variability in iodide and perchlorate intake were considered. Despite consideration of a range of plausible intake values, a considerable fraction of the data frequently do fall outside of these ranges, sometimes by orders of magnitude (e.g., Figure 4, upper panel; Figure 5). Considering that no sensitivity analyses were presented specifically for urinary iodide concentrations (for example), the explanation that variability in physiological and biochemical factors "would	The criteria, and characterization of the agreement between data and simulations on some sort of a sliding scale, such as outstanding, excellent, good, fair, or poor needs to be provided. Metrics should be provided on the quality of agreement with particular model predictions (e.g., fT4 predictions vs. data on average within x-fold, or y % of data within x-fold). Rather than speculate regarding the source(s) of scatter in the experimental data, a sensitivity and variability analyses or Monte Carlo simulations of those outputs for which agreement was poor with the current model (which relies on central tendency parameter estimates only) should be conducted.	S/M

			also have significant effects on the metrics evaluated" is speculative and unsupported.		
12	Model Calibration Results	62	In Cao et al. (2010), urinary iodide and perchlorate data compared by infant feeding method are reported in units of µg/g creatinine, with geometric means and 95% confidence intervals, with no breakdown by postnatal day. Yet, in Figure 4, individual data are plotted as urinary iodide and perchlorate (µg/L) vs. postnatal day.	Please include how a greater level of detail than what was provided in the publication for any data set used in model calibration/validation was obtained.	S
13	Model calibration results	64-5	No rationale was provided for the suggestion that iodide levels in milk are not stable. An inability to characterize iodide concentrations in breast milk and thus the neonatal intake of iodide by breastfeeding babies calls into question the calibration of the lactating mother and infant thyroid hormone models.	A rationale for the lack of stability of iodide in milk should be provided. A rationale for how the breast-fed infant T4 model could be reliable when intake of iodide is so poorly characterized for this lifestage (Figure 7), and excretion of iodide frequently exceeds the predicted range (Figure 5) should also be provided.	S/M
14	Model Calibration Results	67	Individual NHANES data must be used with care because individual values are not a random sample; weights should be used.	Clarification should be provided regarding how NHANES sample weights were considered, if at all, in model calibration relying on that data.	S
15	Dose-Response Evaluation	69	Perchlorate (0-20 µg/kg/d) induced radio iodide uptake inhibition was simulated for the mother and were compared to adult data from Greer et al. (2002) data. However, Greer et al. also collected fT4, T4 and T3 data, which were not	Recommend simulating the thyroid hormone data as well and showing the simulations.	S

			compared.		
16	Dose-Response Evaluation	70-79	The derivation of bounds of the grey bands (depicting ranges for hypothyroxinemia) is not provided. Inconsistencies between the critical fT4 value for formula-fed infants vs. breast-fed infant, and for lactating women on different postnatal days are not explained. For example, for a 30-day-old formula-fed infant, 17.1 pM fT4 is the threshold for hypothyroxinemia, but the threshold for a 30-day-old breast fed infant is 18.1 pM.	The derivation of the bands should be described, also describe why breast-fed and formula-fed infants of the same age and lactating women at various times have differing criteria for being categorized as hypothyroxinemic and implications for establishing adversity. EPA should explain why fT4 levels below 12.1 pM would be adverse for a PND 7 lactating mother, while 8.94 pM is acceptable on day 30. The transient nature of varying definitions of hypothyroxinemia should be discussed in the context of establishing a Safe Drinking Water standard for perchlorate.	S/M
17	Local Sensitivity Analysis of BBDR Model With Perchlorate	83-91	Very little interpretation is provided for these analyses.	The discussion of the sensitivity analyses should be expanded.	S
18	Local Sensitivity Analysis of BBDR Model With Perchlorate	83-91	The sensitivity analysis neglected to report sensitivity to ingestion rates for iodide and perchlorate	Please determine and report the sensitivity of fT4 to maternal and infant iodide and perchlorate ingestion rates.	S
19	Appendix B	App 6	It is not clear why the third compartment of the thyroid was removed, when the earlier PBPK models of Merrill et al. (2003, 2005) and Clewell	This is key model structure should be expanded upon, rather than simplified. We also recommend providing simulations demonstrating	S/M

			et al. (2003a & 2003b, 2007) found it to be necessary to describe thyroid perchlorate and iodide time-course data. It is stated, "Dr. Fisher deemed this to be an unnecessary complication of the model." This statement does not provide adequate reasoning for removing a key physiological feature. Iodide compartmental models have also described the necessity for a three-compartmental thyroid (Lee et al., 1982), which captures the early phase of iodide uptake, consisting of trapping and organification processes and a slower phase of hormone accumulation and secretion.	the lack of difference between the two structures. Lee, P. W., Siegel, J. A., Harpen, M. D., Greenfield, M. A., and Verma, R. C. (1982). In vivo evaluation of intrathyroidal iodide metabolism. J. Clin. Endocrinol. Soc. 55, 1131â€"1137.	
20	Appendix D	App 20-23	The EPA switched to the "normal adult" urinary clearance parameter for the lactating mother and only had a minor difference during the first postnatal day from the "EPA 2009" model. There are not sufficient data to validate the lactating or postnatal mother's urine at this date. It appears more isn't done anything more with that parameter because it can't be validated.	However, another approach that could have been tried is scaling the perchlorate clearance rate during the first two weeks postnatal to that of the iodide urinary clearance shown in EPA 2009 Figure B-5 (data from Aboul-Khair et al. (1964)). Iodide clearance appears to be a little higher at birth (although part of the data is missing) and returns to normal around 6-12 days later.	S

Public Comments

Joel Beauvais,
Deputy Assistant Administrator, Office of Water.

Dear Mr. Beauvais:

I am writing to you in response for your call to public comment regarding the safe drinking water act decision making on perchlorate and the Biological Base Dose-Response model that has been created. I am writing specifically concerning the proposed Maximum Contaminant Level of .7 μg/day. Taking into special consideration women and how their hormone levels will affect their baby.

After researching multiple studies and journal article .7 μg/day appears to be a safe MCL for men, women, and fetus'. These studies sampled urine and analyzed perchlorate levels as well as the amount of iodine present. Because the MCL is so important in combatting hypothyroxinemia proper research is necessary.

Overall, I think the EPA did a thorough job of analyzing how perchlorate affects humans and their iodine uptake into the thyroid gland. This number, .7 μg/day, will keep people safe from the health problems perchlorate can cause. Thank you for you time and consideration.

Sincerely,
Izze Kraiman
West Chester University

Introduction

The EPA has requested for public comment on their proposed MCL or Maximum Contaminant Level with special consideration towards pregnant women, developing fetuses, and breastfeeding mothers and children. Through research the EPA worked to produce a Biologically Based Dose-Response which analyzes how environmental factors such as perchlorate will affect a person on a molecular level. With help from the SAB (Science Advisory Board) the EPA worked to created an MCL to be used in consideration of the Safe Drinking Water Act. The number for MCL where no adverse health effects are seen in humans and no birth defects are seen in babies, is currently .7 μg/day. While some scientists believe this number could be raised slightly without seeing repercussions in human health, extensive research agrees with the number that the EPA has decided upon.

.7μg/day is the amount of perchlorate that a human can ingest and see no health problems. It is important to consider factors such as how a person can come in contact with perchlorate, what can happen if a person has excessive exposure, and how that can also affect a developing fetus. After assessing multiple sources of research .7 μg/day is a point that shows safe levels of the fT4 hormone and iodine in the urine.

Where does perchlorate come from

ClO_4 or Perchlorate is a naturally occurring in the environment as well as made for use in items such as fireworks, herbicides, and airbags in vehicles (Cook, 2015). Because this compound is found naturally occurring, especially in arid areas, and in many items a person comes in contact with, there must be an established safe limit for ingestion. Fruits, vegetables,

shellfish, and milk products all contain perchlorates. When they are cooked in areas with high levels in their water, these foods become even more unsafe (Asami et. al 2013).

Because proper hormones are necessary for a babies development, mother have to be aware of the common ways of ingestion for their children and fetuses. After birth, breast milk and formula are the main source of perchlorates for infants. On average, baby formula prepared with tap water was 1.11 μg/day. This number is high compared to the .7 μg/day suggested as the daily limit, but breast milk can have numbers up to five times higher (Asami et. al 2013).

Health risks perchlorate poses

When too much perchlorate is ingested, this ClO_4 will be a competitor for the uptake of iodide in the thyroid gland. Because of the nature of the thyroid, this will cause a decrease in the production of necessary hormones. These hormones are essential during pregnancy. which is one of the main concerns of hypothyroxinemia, the point at which adverse health effects are seen due to low level of the fT4 hormone. This is any level of fT4 below the 2.5^{th} percentile (Negro et.al 2013). Free thyroxine also known as fT4 is essential to the bodies proper metabolism and cellular function.

These hormones that the thyroid creates are essential to proper brain and neurological development in fetus'. In the first trimester it is essential for the mother to have enough fT4 due to the fact that the fetus relies exclusively on the mothers free thyroxine for its own thyroid regulation (Steinmaus et. al 2014). Because of the heavy reliance on proper thyroid function in mothers, it is important to come up with a Maximum Contaminant Level (MCL) so levels can be monitored.

Studies have been done to prove that increased levels of perchlorate will inhibit the fT4 hormone. One study looks at 2,299 participants all over the age of 12. This study has participants of multiple races, as well as 14% below the poverty line (Blount et. al 2006). Through blood and urine sampling, these scientists were able to show a correlation not only between perchlorate and fT4, but also iodine levels completing the link between the three. While it is agreed upon that these three levels all rely on each other, an acceptable level on ingestion needs to be established for the safety of everyone, especially developing fetus'.

Risks to Developing Fetus

Proper iodine intake during pregnancy is regularly talked about. This is important for many reasons, one being that a fetus has much less stored in its thyroid gland which can lead to iodine deprivation. A study shows that the highest 10% of hypothyroxinemic pregnant mothers saw a decreased average IQ score for their children at the age of 3, generally they were in the lower 10% of their age groups IQ score (Brent 2013). In these women, perchlorate was found in their urine and low iodine levels were noted.

Another study showed that women in the 10th percentile of hypothyroxinemia whose children were between 1 and 2 years old had lower scores on a cognitive development test known as Bayley Psychomotor Developmental Index (Negro et. al 2013). These reduced scores on exams that measure brain function are correlated to an increase in the incidence of diseases such as hyperactivity and attention deficit disorders. They are also linked to a delay in toddlers between the age of 18 and 30 months' ability to use expressive language as that age group should begin to do (Negro et. al 2013).

Analysis of perchlorate level studies

The Nutrition Examination Survey conducted a study assessing the amount of fT4 in men, women, and pregnant women. The women were broken further into iodine levels less then, and greater than 100 μg/L. The non-pregnant women who had iodine levels less than 100 μg/L, still have an fT4 number higher than those pregnant women. The data trend was the same with women who had iodine levels greater than 100 μg/L, pregnant women consistently had less fT4 then the equivalent non-pregnant females, as well as men (Suh et. al 2014). This data shows that pregnant women lack in fT4 hormone as the fetus requires it. With an excess ingestion of perchlorate these numbers would be even lower, which will have negative affects against the fetus.

There are a few ways to analyze iodine in the body to help find a correlation between iodine and perchlorate. One test is to look at the amount of iodine in someone's urine. This number will be around 90% of the amount consumed each day. Through the analysis of a sample of pregnant women, a curve was created to predict the correlation between amount of iodine and fT4 levels. As seen unanimously as iodine levels go up, fT4 levels go up as well. This study saw that at an ingestion level of perchlorate 1.0 μg/day, the fT4 levels began to match up with those associated with hypothyroxinemia (Lumen 2013). Based on this data, a number less than 1.0 μg/day would be an acceptable MCL. This aligns with the proposed .7 μg/day that the EPA suggested as a point without adverse health effects.

A 2007 study that the EPA used to determine an MCL for perchlorate studied a group of 21 women and 16 men between the ages of 18 and 57 a variety of doses of perchlorate for 14 days. The dose amounts were 0.007, 0.02, 0.1 and 0.5 mg perchlorate/kg body weight (Greer et. al). The individuals in the study that saw no adverse health effects on thyroid iodine uptake

where those those who received .7μg/day. Any number after saw an 83.6% decrease in their thyroid function, a number that could potentially effect health.

While this study has been key in determining the MCL, the sample of people was small, and it did not take into consideration any intersectional approach for example race. It was over a short period of time which may not show the long term health effects that perchlorate can have on the body.

One study that takes an interesting aspect on perchlorate intake had three different groups. One was given a placebo dose, one was given .5 μg/day and one was given 3 μg/day. While these were extremely small sample sizes with only 5 participants in each, the evidence was very telling. The placebo group as expected staying within a fraction of their baseline values for fT4. The group that received .5 μg/day almost no change while the group that was given 3 μg/day, saw a slight decrease in fT4 (Braverman et. al 2011). This study and the information it provides is important. While the sample size may be small, these levels were assessed long term for 6 months of daily ingestion.

This information helps when assessing an MCL and how over time it may affect hormone levels. Because these numbers correlate with previous studies showing that 3μg/day shows problems in human health. While the .5 μg/day is slightly lower than the .7 μg/day that the EPA suggests, the general curve of the data agrees.

Conclusion

There is a strong correlation between the amount of perchlorate ingested, iodine intake, and essential hormones in the human body. Lack of these hormones and iodine can lead to serious health problems especially in pregnancy women and their fetus' including cognitive

problems and lower IQ scores. The EPA has decided that .7 μg/day is a safe ingestion level of perchlorates and that hypothyroxinemia will not be seen, keeping mothers and children safe. Through research and analyzing multiple well respected studies, there has been no health problems associated with this number. Until solid research comes out with a strong sample size and number showing otherwise, .7 μg/day will be the universally accepted safe amount of perchlorate ingestion without any adverse health effects.

RE: Request for Public Comments to be sent to EPA on Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate, Docket ID Number: EPA-HQ-OW-2016-0438

Dear Sir or Madam:

The Chlorine Institute ("CI" or the "Institute") is a 190 member, not-for-profit trade association of chlor-alkali producers worldwide, as well as packagers, distributors, users, and suppliers. The Institute's North American Producer members account for more than 93 percent of the total chlorine production capacity of the U.S., Canada, and Mexico. The Institute's mission chemicals, namely chlorine, sodium hydroxide and potassium hydroxide, and hydrogen chloride, are used throughout the U.S. economy and are paramount to the protection of public health.

While The Chlorine Institute appreciates EPA's efforts in developing a standardized model for the purpose of determining an appropriate perchlorate drinking water level, the Institute believes there are flaws in the BBDR model that should be considered. CI provides the following comments to further explain the flaws in the model.

Lack of data or limited data is noted for the life-stage human values.

- The proposed BBDR model used physiological parameters to set the life-stage-specific human values. However, throughout the document on several occasions, the lack of data or limited data is noted for the life-stage human values. As noted by EPA, "Physiological parameters are life-stage specific, and were taken from appropriate sources (identified in the data tables) where possible. However, many of the iodide/thyroid hormone and perchlorate parameters where not available for specific life-stages, and so were extrapolated from other life-stages or in-vitro data." (US EPA, 2016)[1]. One parameter with limited or no data is hypothyroxinemia during pregnancy, maternal lactation or infancy as noted by EPA. In addition, there is no clinical definition of hypothyroxinemia and, as a result, various ranges of free T4 (fT4) are found in the literature. As noted by EPA, " within the context of pregnancy, some authors use the

2.5th percentile of the fT4 population distribution while others use the 10th percentile and the reference ranges vary between populations and studies (Moleti et al., 2011)[2]. Elevated TSH levels, the marker of hypothyroidism, can occur in women with fT4 levels in the same range as other women with normal TSH levels (e.g., see 9 Figure 1 in Moleti et al. (2008), so there is also not a specific fT4 level below which this transition occurs" (US EPA, 2016). Therefore, assumptions have been made to set the parameters for the model that may weaken the predictive outcomes of the model.

The BBDR model does not account for both aggregate and cumulative exposures to chemicals with the same mode of action to perchlorate.

- The proposed BBDR model does not account for chemicals with similar modes of action that inhibit the sodium iodide symporter (NIS) which transports iodine into the thyroid. Perchlorate is known to inhibit the NIS. However, so are nitrate and thiocyanate which are ubiquitous in a healthy diet and drinking water. Background levels of these chemicals can be much higher than perchlorate and are unlikely to be distinguishable. In regards to their potency, in vitro studies comparing the relative abilities of perchlorate, nitrate, and thiocyanate to inhibit cellular iodine uptake show that, after adjusting for biological half-life, perchlorate is half as potent as thiocyanate and 240 times as potent as nitrate (De Groef et al. 2006)[3]. In addition, ATSDR (2008)[4] noted that, "Nitrate and thiocyanate are widely distributed in nature and, because both anions also inhibit RAIU [radioactive iodide uptake], as demonstrated by Tonacchera et al. (2004)[5], should also be included in the discussion of the effects of inhibition of the NIS by anions." The BBDR model does not account for both aggregate and cumulative exposures to chemicals with the same mode of action to perchlorate.

Appropriate data are not available to validate the model.

- The infant, 7 to 90 days of age, breast-fed and formula fed, as well as the lactating mother were selected for the BBDR model development to address the most sensitive period of thyroid function maturation that may have consequences if exposure to perchlorate occurs. There is, however, a lack of epidemiologic data that current environmental exposure to perchlorate results in adverse effects to infant thyroid function (Tarone et al. 2010[6]; Charnley 2008[7]). Without the appropriate data, the model cannot be validated. If the appropriate data are not available to validate the model, then data must be collected from biomonitoring studies or generated in animal prior to use of the model to most accurately predict outcomes from exposures to perchlorate.

Homeostatic control mechanism does not account for in the proposed BBDR model.

- Clearly, a reduction in thyroid hormones over a substantial amount of time during fetal development is potentially deleterious to the developing fetus. However, the thyroid

has stores of iodide received from the mother such that short-term fluctuations in iodide uptake in the first post-natal days will cause no effect. Physiologically, when uptake of iodine is decreased, the body adapts by upregulating the number of the NISs to pump more iodide into the thyroid. This is a homeostatic control mechanism and is not accounted for in the proposed BBDR model.

Additional resources to be reviewed and considered in proposed BBDR model.

- Lumen et al. (November 2016)[8] have published a population based pregnancy model that estimates iodine nutrition and thyroid status in late gestation pregnant women in the United States. The BBDR model accounts for a wider range of iodine deficiencies and homeostatic mechanisms. To characterize total (T4) and free (fT4) thyroxine levels for a given iodine status at the population-level, the distribution of iodine intake for late-gestation pregnant women in the U.S was reconstructed using various reverse dosimetry methods and available biomonitoring data. The reconstructed distributions of iodine intake allowed for the estimation of nutrient inadequacy for late-gestation pregnant women in the U.S. via the probability approach. The prevalence of iodine inadequacy for third-trimester pregnant women in the U.S. was estimated to be between 21% and 44%. This paper should be reviewed and considered for incorporation into the proposed BBDR model (Lumen, 2016).

- In May 2011, The Chlorine Institute commissioned an evaluation (attached) conducted by ENVIRON International Corporation on the health advisories and standards for perchlorate levels in drinking water. This evaluation was submitted to EPA in response to its Final Regulatory Determination, which was issued in February 2011 for the agency to proceed with derivation and proposal of a National Primary Drinking Water Regulation. In that evaluation, ENVIRON provides what the Institute believes to be an acceptable perchlorate drinking water level based on appropriate data. The ENVIRON evaluation is another resource that should be reviewed and considered by EPA to further develop the BBDR model.

Peer review process

- The Federal Register notice of September 30, 2016 states that "Versar, Inc., will provide a report to EPA summarizing the peer reviewer's [sic] evaluation of the scientific and technical merit of the draft model and draft report and their responses to the charge questions." Due to the complexity of the model and the SAB Perchlorate Panel's call for transparency, like the SAB process, the panel should be responsible for drafting the report, not the contractor Versar. Additionally, it is unclear whether Versar has the necessary expertise to summarize the complex science and science policy questions

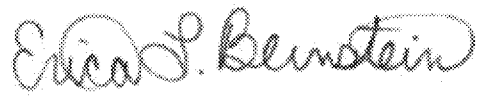
involved with the BBDR model and therefore may not accurately reflect the issues, conclusions, and recommendations of the panel.

Conclusion

In conclusion, the Institute believes the BBDR model does not account for both aggregate and cumulative exposures to chemicals with the same mode of action to perchlorates and that there is a lack of data to validate the model. CI recommends that EPA consider the comments and resources noted above, as well as review the attached ENVIRON study, to further improve the BBDR model in the agency's effort to propose an appropriate perchlorate drinking water level.

Thank you for the opportunity to comment on this proposed model and your careful attention.

Best Regards,



Erica Bernstein

Executive Summary

Perchlorate's effect on the thyroid to inhibit iodide uptake has been known for decades and has been the reason for the use of high doses of perchlorate, therapeutically, to treat hyperthyroidism, in particular in the treatment of Graves disease, a medical condition resulting from hyperthyroidism. Other non-medical uses of perchlorate, such as in rocket fuel and other applications as an oxygen source in high burn applications, may have resulted in releases of perchlorate to the environment, particularly to ground water.

Studies in laboratory rats have raised a concern that exposure to perchlorate may result in adverse effects in people with normally functioning thyroids. While the function of the thyroid and the homeostatic mechanisms for maintaining thyroid function at biologically relevant levels are similar across species, rats are more sensitive to perchlorate-induced hormone changes than humans. Fundamental differences between rats and humans are the reduced ability in rats to store thyroid hormones in the thyroid gland and the inability to have a substantial "backup" supply maintained by special proteins in the blood. Thus, the dose-responses for adverse effects reported in rats may not be directly applicable to use in human risk assessment of exposure to perchlorate.

Human epidemiological, occupational, and clinical studies, taken together, indicate that perchlorate exposures at environmental and occupational levels do not produce changes in thyroid function that would be considered adverse and affect normal thyroid functioning. While very short-term exposure to perchlorate may produce a transient change in thyroid hormone levels, the resilient, adaptive mechanisms that maintain homeostasis (a dynamic and controlled balance) in humans restore the balance of thyroid hormone levels in the thyroid and circulating blood. In people, even with long term exposure to perchlorate, the thyroid system is able to control these fluctuations and conserve thyroid hormone levels in the blood to maintain normal function. Thus, inhibition of thyroid iodide uptake is not an adverse effect unless extreme conditions occur, such as chronic inhibition from extremely high (i.e., therapeutic levels) exposures. In the case where adequate iodine is in the diet, exposure to perchlorate at environmentally relevant levels should not be of concern.

Despite these experimental and physiological data, the U.S. Environmental Protection Agency (USEPA), California Environmental Protection Agency (Cal EPA), and Massachusetts Department of Environmental Protection (Mass DEP) have derived perchlorate drinking water advisories or standards based on human clinical data for inhibition of iodide uptake into the thyroid from a 2-week drinking water exposure. This biological endpoint was recommended by a National Research Council (NRC) committee in 2005, which noted that the effect was not adverse, but was conservatively useful for developing a safe drinking water level. However, data published at the same time or after the NRC recommendation clearly indicated that environmental perchlorate exposure levels can be handled without injury by adaptive biological mechanisms and confirmed the NRCs conclusion that such levels do not have an adverse impact on thyroid function, even in iodide-deficient pregnant women and infants.

This present report evaluated the data considered by the NRC committee and regulatory agencies and more recent data published since their evaluations. We are proposing an

acceptable drinking water level of 620 µg perchlorate/L, based on a dose-response analysis of the No Observed Adverse Effect Level (NOAEL) from human occupational studies. While our proposed value is higher than those proposed by USEPA, Cal EPA, and Mass DEP, our recommended drinking water level is scientifically defensible and was derived with conservative choices for defining the effect threshold that would be protective of sensitive subpopulations.

1 Introduction

The ability of perchlorate to affect human thyroid function has been known for decades. In the 1950s and 60s, high oral doses of perchlorate (2000 mg/day in adults) were used medicinally to treat hyperthyroidism ("overactive thyroid"). Although high-dose treatments were discontinued in the late 1960s, lower doses (600 mg/day) continued to be used without serious side effects to treat anti-thyroid effects of the drug, amiodarone (Leung et al., 2010). Perchlorate does not affect organ systems in humans other than the thyroid.

The use of perchlorate in non-medical applications, such as an oxygen source in high burn rate combustion applications, such as solid rocket fuels, explosives, road flares, pyrotechnics, and air bag inflation systems, may have resulted in the release of perchlorate in the environment, where it has been detected in ground water of 26 states (Trumbo, 2009; Braverman, 2007).

Regulatory agencies in the United States, based largely on animal data and data in a very short-term study in human volunteers, have assumed that the presence of perchlorate in drinking water could have an impact on normal thyroid function with resultant adverse impacts on health. While the potential amount of perchlorate intake from drinking water is likely to be orders of magnitude lower than those historically used in medical therapy, California Environmental Protection Agency's (Cal EPA) Office of Environmental Health Hazard Assessment (OEHHA) derived a Public Health Goal (PHG) for perchlorate in drinking water in 2004, which became the Maximum Contaminant Level (MCL) in 2005. Likewise, Massachusetts Department of Environmental Protection (Mass DEP) derived a perchlorate drinking water standard in 2006. In 2008, the U.S. Environmental Protection Agency (USEPA) issued a Preliminary Regulatory Determination (USEPA, 2008a), indicating that a national primary drinking water regulation for perchlorate would "not present a meaningful opportunity for health risk reduction for persons served by public water systems." USEPA did calculate a Health Advisory (HA) Level for drinking water (USEPA, 2008b). IN February of 2011, USEPA issued a Final Regulatory Determination to proceed with derivation and proposal of a National Primary Drinking Water Regulation (NPDWR) (USEPA, 2011a) within 24 months.

Although the USEPA, Cal EPA and Mass DEP values differ, they are all based on the same clinical study in which volunteers ingested perchlorate in drinking water for two weeks, (Greer et al., 2002). The differences between the values derived by these groups result from different methodological approaches used to determine the allowable total daily dose of perchlorate, the proportion of that dose allowed in drinking water, the drinking water ingestion rate, and treatment of data uncertainties (Sections 2.1-2.3). The regulatory values are based on opinions of the National Research Council (NRC) presented in a 2005 assessment of the perchlorate data in humans and animals (NRC, 2005).

Newer and more relevant data are now available. For this report, ENVIRON examined and performed a critical review of the latest data. A summary of the biology and function of the thyroid hormone system relevant to perchlorate, relevant animal and human data used by the USEPA, Cal EPA, and Mass DEP to set acceptable values for perchlorate in drinking water, and data published since the NRC (2005) assessment are presented in the Appendix. A critical evaluation of the existing USEPA, Cal EPA, and Mass DEP perchlorate drinking water

ED_005043_00062728-00037

standards is presented in Section 2. Based on this review, ENVIRON has proposed a scientifically defensible acceptable drinking water level for perchlorate, presented in Section 3.

2 Evaluation of the Drinking Water Levels for Perchlorate by Regulatory Agencies

As detailed in the Appendix, the effect of perchlorate on the thyroid is to inhibit the uptake if iodide from the blood into the thyroid follicle cells, where iodine is used to produce the hormone thyroxine (T_4), which is then converted enzymatically to triiodothyronine (T_3). The USEPA, Cal EPA, and Mass perchlorate drinking water values are all based on the data from Greer et al. (2002), in which 37 adults were given 0.007, 0.02, 0.1, or 0.5 mg/kg/day perchlorate (groups of 7-10 subjects) in drinking water for 14 days. After 2 and 14 days of exposure, the uptake of radioactive iodide (RAIU, a representative fraction of iodide in the whole body) into the thyroid was measured. In addition, blood levels of perchlorate and thyroid hormones T_3, T_4, and thyroid stimulating hormone (TSH) were measured before, during, and after cessation of exposure. While significant inhibition of RAIU was observed at ≥0.02 mg/kg/day, there were not associated with changes in thyroid hormone levels. A lack of change in thyroid hormones is not surprising, as healthy adult thyroids contain sufficient stores of T_3 and T_4 to maintain normal hormone levels in the body for up to six months.

Studies published since the NRC (2005) assessment indicate that the human thyroid system compensates for inhibited iodide uptake from chronic environmental and occupational perchlorate exposure, maintaining adequate thyroid function in clinical volunteers (Braverman et al., 2006), perchlorate workers (Lamm et al., 1999; Braverman et al., 2005), and in iodine-deficient women and pregnant women and their infants (Crump et al., 2000; Tellez et al., 2005; Buffler et al., 2006; Van Landingham and Gibbs, 2008; Pearce et al., 2008, 2010, 2011). Compensation for inhibition of iodide uptake is accomplished by stimulation of the thyroid to increase the capacity of iodide transport into the thyroid follicle cells. This is one of the functions of adaptive, resilient biological feedback mechanisms that are inherent in all humans to maintain homeostasis and normal thyroid health, as discussed in the Appendix. Thus, a 2-week exposure (Greer et al., 2002) is not characteristic or predictive of long term functioning at such low levels of perchlorate exposure. Nevertheless, the NRC derived a Reference Dose (RfD) of 0.0007 mg/kg/day (0.7 µg/kg/day) based on a perchlorate No Observed Effect Level (NOEL) producing no significant short-term inhibition (less than 2%) of RAIU. The NOEL of 0.7 µg/kg/day was divided by an uncertainty factor (UF) of 10 to account for sensitive subpopulations. In the same assessment, NRC stated that

> ***"it is not likely that the decreases in thyroid iodide uptake reported in short-term studies would be sustained; rather, iodide uptake would be expected to return to normal. To cause declines in thyroid hormone production that would have adverse health effects, iodide uptake would most likely have to be reduced by at least 75% for months or longer."***

ED_005043_00062728-00038

Derivation of a scientifically-valid, acceptable perchlorate drinking water level should be based on a dose estimate that is close to, but below, the actual threshold for onset of the most sensitive adverse effect (subclinical hypothyroidism). For perchlorate, this calls for chronic exposure data in humans that identifies an exposure level in which the thyroid has achieved non-adverse compensation for iodide uptake inhibition, while maintaining adequate thyroid hormone production. Nevertheless, USEPA, Cal EPA, and Mass DEP adopted inhibition of thyroidal iodide uptake reported by Greer et al. (2002) as the critical endpoint for derivation of their respective drinking water values. Short-term inhibition of iodide uptake is an inappropriate endpoint for deriving a safe drinking water level for perchlorate because (1) it is not an adverse effect, (2) it does not result in changes in thyroid hormone levels or function, and (3) the thyroid system compensates for the inhibition to maintain adequate thyroid hormone levels. The USEPA, Cal EPA, and Mass DEP perchlorate drinking water levels, based on a short-term NOEL, are no more health protective than higher levels that are based on a long-term No Observed Adverse Effect Level (NOAEL). As discussed in Section 3 and the Appendix, the available human data for perchlorate indicate higher exposure levels than the Greer et al. (2002) NOEL that result in initial inhibition of iodide uptake, but produced no adverse effect on thyroid hormone levels or thyroid tissue health (i.e., a NOAEL).

2.1 U.S. EPA Interim Drinking Water Health Advisory for Perchlorate

The USEPA (2008) Interim Health Advisory (HA) for perchlorate in drinking water is 15 µg/L. The HA is based on the NRC (2005) and USEPA (2005) RfD of 0.7 µg/kg/day (i.e., Greer et al. [2002] NOEL divided by 10). The fraction of the total dose (such as an RfD) of a regulated chemical allowable in drinking water, accounting for other non-drinking water exposures, is called the Relative Source Contribution (RSC). For example, if a hypothetical daily estimated perchlorate exposure from sources other than drinking water were 25% of the RfD, the perchlorate exposure allowed from drinking water would be 75% of the RfD, resulting in an RSC of 0.75. In the U.S., the main source of non-drinking water perchlorate exposure is food, such as vegetables and dairy products, with daily intake estimates ranging from 0.08-0.4 µg/kg/day (Trumbo et al., 2010). Data for perchlorate intake in food are available from the National Health and Nutritional Examination Survey (NHANES), the First Unregulated Contaminant Monitoring Regulation (UCMR 1), and the U.S. Food and Drug Administration (USFDA) Total Diet Study. USEPA analyzed the NHANES and UCMR 1 databases to derive an estimate of 0.263 µg/kg/day for dietary perchlorate ingestion in pregnant women. This value is 38% of the USEPA RfD, allowing for 62% of the RfD to be allowed in drinking water (RSC = 0.62). Finally, USEPA used a body weight (BW) and daily drinking water ingestion rate (IR) of 70 kg and 2L/day, respectively, both of which are default values used in deriving drinking water health advisories. Using these values, the interim drinking water HA level was calculated as:

$$HA = \frac{\frac{NOEL}{UF} \times RSC \times BW}{IR}$$

$$HA = \frac{\frac{7\mu g/kg/day}{10} \times 0.62 \times 70kg}{2L/day} = 15\ \mu g/L$$

USEPA selected the inappropriate endpoint (inhibition RAIU) on which to base the RfD and the HA, for reasons discussed in Section 2.0. The selection of an RSC of 0.62 is based on NHANES and UCMR 1 data for pregnant women living in areas unlikely to have perchlorate in drinking water. With an estimate of perchlorate in food of 0.263 µg/kg/day, selection of an RfD of 0.7 µg/kg/day allows for only 62% of total perchlorate intake to come from drinking water. However, there is uncertainty as to whether an RSC is at all necessary, as the perchlorate levels in diet of volunteers were not monitored and may have resulted in total daily perchlorate intake higher than the known doses administered in this study. Thus, the Greer et al. (2002) NOEL on which the USEPA RfD was based may have been underestimated.

2.2 Evaluation of the California EPA Drinking Water MCL for Perchlorate

In 2004, Cal EPA promulgated a primary MCL for perchlorate in drinking water, based on the derivation of a Public Health Goal (PHG) of 6 µg/L, as described by OEHHA (OEHHA, 2004) and Ting et al. (2006). The MCL was based on Cal EPA's benchmark dose (BMD) modeling of the data from the study of Greer et al. (2002), in which a 5% decrease in RAIU was considered biologically significant. From the BMD modeling, a statistical lower limit (i.e., confidence bound) of the benchmark dose (BMDL), 3.7 µg/kg/day, was estimated. The BMDL incorporates information on the shape of the dose-response curve (i.e., potency), as well as variation in the experimental measurements. The BMDL served as a surrogate No-Observed-Effect-Level (NOEL) (USEPA, 2000), and was divided by an UF of 10 to account for uncertainties in sensitivity of iodide-deficient hypothyroid pregnant women and their fetuses and infants. Data for perchlorate in some foods were analyzed by Cal EPA (Kirk et al., 2003, as cited by USEPA, 2008) to qualitatively determine that more than half of environmental perchlorate exposure is likely to come from drinking water rather than food. Thus, an RSC of 0.60 was selected (OEHHA, 2004). Finally, Cal EPA used a body weight-to-daily drinking water ingestion rate ratio of 25.2 kg/day/L (61kg body weight; 2.42L/day) to represent drinking water consumption for the 95th percentile of pregnant women (OEHHA, 2000). Using these values, the Cal EPA primary MCL was calculated as:

$$MCL = \frac{\frac{3.7\mu g/kg/day}{10} \times 0.60 \times 61\ kg}{2.42L/day} = 6\ \mu g/L$$

Cal EPA selected the inappropriate endpoint (inhibition of RAIU) on which to base MCL. Further, Cal EPA's selection of an RSC of 0.60 is based on the assumption that perchlorate in drinking water accounts for most of the perchlorate exposure. Data for perchlorate in the diet of various U.S. subpopulations, including adults, children, and pregnant and lactating women, are now available from the NHANES and UCMR databases, as well as the U.S. Food and Drug Administration (USFDA) Total Diet Study. Selection of an RSC should be based on a reasonable quantitative estimate of relative food contribution to the total allowable perchlorate dose, rather than an arbitrarily-chosen fraction.

2.3 Evaluation of the Massachusetts DEP Drinking Water MCL for Perchlorate

In 2006, Massachusetts DEP promulgated a Drinking Water Standard (DWS, Massachusetts' nomenclature for an MCL) for perchlorate of 2 µg/L, as described by Zewdie et al. (2008). Mass DEP defined an RfD for perchlorate by dividing the Greer et al. (2002) NOEL of 7 µg/kg/day for inhibition of RAIU by a composite UF of 100. In addition to lowering the NOEL by a factor of 10 to account for uncertainties in sensitivity of iodide-deficient of hypothyroid pregnant women and their fetuses and infants (as done by USEPA and Cal EPA), another factor of 10 was applied for "database insufficiencies", extrapolation of results from healthy adults, and basing the drinking water standard on what Mass DEP defined as an adverse effect level rather than a NOEL. An RSC of 0.20 was applied to the Mass DEP RfD, allowing for 20% of the total daily perchlorate dose to come from drinking water. Finally, Mass DEP used default adult body weight and daily drinking water ingestion rate values of 70 kg and 2L/day, respectively. Using these values, the Mass DEP DWS was calculated as:

$$DWS = \frac{\frac{7\mu g/kg/day}{100} \times 0.20 \times 70kg}{2L/day} = 0.49\ \mu g/L$$

Although the calculated DWS is <0.5 µg/L, Mass DEP set the DWS at 2 µg/L. Mass DEP stated that standard use of sodium hypochlorite for public drinking water disinfection may result in finished drinking water with perchlorate levels in excess of 1 µg/L. In order to avoid creation of compliance issues creating a disincentive for necessary water supply disinfection, the DWS was set at 2 µg/L.

Mass DEP selected the inappropriate endpoint (short-term inhibition of RAIU) on which to base their RfD and DWS. In addition to applying an UF of 10 for uncertainties in sensitivity of subpopulations, Mass DEP applied an additional UF of 10 for data gaps. Mass DEP determined inhibition of RAIU in 4 of 7 volunteers in the low-dose group of the Greer et al. (2002) study to be an adverse effect rather than a NOEL, in spite of the fact that the group as a whole did not exhibit significant RAIU inhibition or any reduction in thyroid function. Categorizing short-term inhibition of RAIU as an adverse effect is in opposition to the findings of the NRC (2005) panel, as well as the occupational and epidemiological studies discussed above and in the Appendix that indicate the compensatory ability of the thyroid hormone system to maintain normal thyroid function in adults, pregnant women, and their infants. This decision resulted in an inappropriately conservative RfD on which to base the DWS.

The 2004 selection of an RSC of 20% is based on Mass DEP's determination at the time that the available data did not support the derivation of a less conservative value. In retrospect, Zewdie et al. (2008) discussed the NHANES, UCMR, and USFDA Total Diet Study data. These authors determined that, given the low Mass DEP RfD of 0.07 µg/kg/day relative to food perchlorate intake estimates of 0.2-0.4 µg/kg/day, an RSC of 20% or less was justified. However, Mass DEPs choice to use an inappropriate endpoint and an unnecessarily high UF also resulted in an unnecessarily conservative RSC.

2.4 Limitations of Existing Drinking Water Advisories and Standards

The perchlorate drinking water health advisory and standards derived by USEPA, Cal EPA, and Mass DEP are overly conservative and not based on appropriate interpretation of the available human clinical, epidemiological, and occupational data. All are flawed because they are based on a short-term, non-adverse effect (inhibition of RAIU) from a 2-week exposure in healthy adult volunteers that does not inform on the compensatory mechanisms of the thyroid hormone system to maintain homeostasis during chronic exposure, which are indicated in the human data from chronic exposures. In addition, Mass DEP incorrectly categorized short-term inhibition of RAIU as an adverse effect and applied an additional, unnecessary UF of 10. A consequence of selecting the Greer et al. (2002) NOEL of 7 µg/kg/day as the point-of-departure for deriving a drinking water standard, and applying UFs of 10 or 100, is that the resulting total allowable perchlorate dose (0.07-0.7 µg/kg/day) is at or less than the levels consumed in food (0.08-0.4 µg/kg/day). This forces down the fraction of total perchlorate allowed in drinking water by application of smaller and unnecessarily conservative RSCs. These issues resulted in allowable drinking water levels of 2-15 µg/L that may be problematic for compliance by some public water systems, while providing little, if any, real meaningful reduction in public health risk.

3 Acceptable Drinking Water Level for Perchlorate

ENVIRON derived an acceptable drinking water level for perchlorate based on dose-response data from chronic human exposures. The present assessment is based on data from chronic human exposures reported by Braverman et al. (2004) and Lamm et al., 1999. These data are preferable for several reasons. The study subjects, perchlorate production workers, were exposed for a minimum of 1.7 years and an average of 6 years.

Exposure of the perchlorate workers were primarily via inhalation. However, estimates of the total daily perchlorate dose were calculated using perchlorate levels measured in blood and urine by the study authors (Lamm et al., 1999; Braverman et al., 2004). Regardless of whether perchlorate is inhaled or ingested, equivalent levels in the blood will have the same effect on the thyroid system. Thus, inhalation exposures can be extrapolated to oral exposures using data for perchlorate blood and urine levels of perchlorate as well as knowledge of how quickly perchlorate is cleared from the body (as done by Crump and Gibbs [2005], discussed below).

The perchlorate workers and controls were observed before, during, and after three consecutive 12-hour work shift exposures for inhibition of RAIU (Braverman et al., 2004) and thyroid function (T_3, T_4, TSH, FTI [free T_4 index], and thyroglobulin levels) (Lamm et al., 1999; Braverman et al., 2004). Blood and urinary perchlorate levels for individual workers were available for analysis. Braverman et al. (2004) also measured levels of the inhibitors of iodide uptake that are ubiquitous in the diet, thiocyanate and nitrate, in order to isolate the effects of perchlorate exposure. Because thiocyanate and nitrate levels were not different between control and exposed workers, any differences seen RAIU or thyroid function could be attributed to perchlorate exposure.

Although RAIU inhibition was reported in the exposed workers, upregulation of iodide uptake capacity was also exhibited. Prior to the first observed work shift, the average thyroid RAIU for twenty-nine exposed workers was 21.5%, compared to 14.4% for twelve controls (Braverman et al., 2004). Even though the median exposures of 0.33 mg/kg/shift occurred in 3-day on/3-day off shifts, the workers experienced a compensated ability to get the required amount of iodide into the thyroid, even in the presence of perchlorate-induced inhibition. The study authors suggested that higher pre-shift values of RAIU in exposed workers are indicative of upregulation of iodide uptake. During the exposure, the inhibition of iodide uptake by perchlorate reduced the rate of RAIU from 21.5% down to 13.5%, which was essentially equal to the unexposed controls (14.4%). These findings, coupled with the lack of change in thyroid hormone levels or thyroid gland size, showed that chronic occupational perchlorate exposure was dealt with effectively by the hypothalamus-pituitary-thyroid axis, providing protection from subclinical hypothyroidism.

Crump and Gibbs (2005) analyzed the occupational data of Braverman et al. (2004), Lamm et al. (1999), and the data of Greer et al. (2002). They used simple, single-compartment mathematical models of the body to extrapolate the inhaled daily doses from the blood and urine perchlorate levels. The accuracy of the models to predict daily perchlorate doses were confirmed against the multi-day perchlorate blood level data from subjects in the Greer et al. (2002) study. They then performed BMD modeling of the worker dose data to estimate a perchlorate dose that would have no effect on thyroid function. Rather than modeling data for inhibition of iodide uptake (as was done by Cal EPA), Crump and Gibbs (2005) modeled changes in blood levels of thyroxine (T_4) or thyroid stimulating hormone (TSH), two thyroid hormones that are the primary indicators of thyroid function. Because no clinically abnormal T_4 or TSH levels were measured in the workers, Crump and Gibbs (2005) selected blood levels that were different from 95% of the study population as their surrogate threshold of response for the purposes of modeling the data. The resulting BMDLs were 24 mg/day (based on free T_4 in the blood) and 57 mg/day (based on TSH in the blood). Assuming an average worker body weight of 96 kg (201.3 lbs for exposed workers in Braverman et al., [2004]), the more conservative of the two no-response levels, 24 mg/day, would result in a body weight-adjusted BMDL of 0.25 mg/kg/day, or 250 µg/kg/day, that could be used as a point of departure for deriving an RfD and acceptable drinking water level. An RfD of 25 µg/kg/day was calculated by dividing the BMDL of 250 µg/kg/day by an uncertainty factor of 10 to be conservatively protective of potentially sensitive subpopulations, if any. The ENVIRON RfD is higher than the RfD USEPA (2005, 2008) an Cal EPA (2004) because of the selection of subclinical hypothyroidism from chronic perchlorate exposure as the critical endpoint, which is a more appropriate endpoint than inhibition iodide uptake from short-term exposure.

The derive an appropriate drinking water level for perchlorate, representative body weights and ingestion rates from the most sensitive population should be used, if data are available. Although the human data do not indicate that infants exposed *in utero* of iodide-deficient women are affected by environmental perchlorate exposures (see Appendix), this subpopulation was selected to base an acceptable drinking water level. Thus, ENVIRON calculated an acceptable perchlorate drinking water level using estimates of perchlorate in food, body weight, and water ingestion rate data for pregnant women.

ED_005043_00062728-00043

Using data from the NHANES and UCMR data sets, USEPA estimated perchlorate intake from food in 90% of pregnant women in the U.S. would likely be 0.263 µg/kg/day or less (USEPA, 2008a). This is 1% of the ENVIRON RfD of 25 µg/kg/day. Thus, with 99% of the total perchlorate dose allowable in drinking water, an RSC of 0.99 was applied to the RfD to calculate an acceptable drinking water level.

The representative body weight and daily drinking water ingestion rate used in the drinking water calculation were taken from the USEPAs *Estimated Per Capita Water Ingestion and Body Weight in the United States – An Update* (USEPA, 2004). For pregnant women, 50% percentile for body weight was 63 kg, while the 95th percentile for daily drinking water ingestion rate was 2.5 L/day, respectively (USEPA, 2004). These are conservative choices, assuming higher drinking water (and perchlorate) ingestion than the majority of pregnant women.

Using the values discussed above, an acceptable drinking water level was calculated as:

$$acceptable\ drinking\ water\ level\ (\mu g/L) = \frac{\frac{BMDL}{UF} \times RSC \times BW}{IR}$$

$$acceptable\ drinking\ water\ level\ (\mu g/L) = \frac{\frac{250\ \mu g/kg/day}{10} \times 0.99 \times 63kg}{2.5\ L/day}$$

$$acceptable\ drinking\ water\ level\ (\mu g/L) = 620\ =\ 620 \text{ parts per billion}$$

The proposed acceptable drinking water level of 620 µg/L is 2-3 orders of magnitude higher than the federal and state drinking water advisory and standards for perchlorate. The reason for the marked difference in the proposed drinking water level and those of Cal EPA, Mass DEP, and USEPA is the choice of study and critical endpoint. The published data for humans, including iodine-deficient pregnant women and their infants, support the choice of subclinical hypothyroidism (an adverse effect) as the critical effect, rather than RAUI, a non-adverse effect which has been shown to occur in the absence of any adverse effects on human growth, development, or metabolism (Braverman et al., 2004; Tellez et al. 2005; Buffler et al. 2006; Cao et al. 2010; Pearce et al. 2010, 2011). The proposed value was calculated based on conservative parameter value choices, including a BMDL modeled using a conservative threshold for thyroid hormone response, addition of an UF of 10 (assuming existence of perchlorate-sensitive subpopulations), and an assumed high drinking water ingestion rate (95th percentile for pregnant women).

4 Summary and Conclusions

The weight-of-evidence from the human clinical, occupational, and epidemiological data does not support the hypothesis that perchlorate in drinking water has resulted in adverse effects, including subclinical hypothyroidism, even in subpopulations that are presumed by others to be more sensitive to changes in thyroid iodide uptake. The critical endpoint on which the proposed drinking water level is based is the potential for subclinical hypothyroidism, as would be indicated by decreased blood T_4 concentration and/or increased blood TSH concentration. Changes or lack thereof in thyroid hormone levels is a more appropriate biomarker for potential effects on the thyroid. Inhibition of iodide uptake is not the appropriate endpoint for toxicity assessment in humans because of the ability of the thyroid hormone system to adapt to transient changes because of normally functioning compensatory, feedback, and homeostatic mechanisms. Thus, inhibition of iodide uptake is not necessarily an indicator of impending downstream toxicity at exposure levels in which thyroid hormone levels are maintained without overstressing the compensatory mechanisms. The human data discussed previously and in the Appendix provide strong evidence that normal thyroid hormone function can be maintained during chronic exposures to perchlorate that may also cause inhibition of iodide uptake in adults (Lamm et al., 1999; Braverman et al., 2004; Tellez et al. 2005; Pearce et al. 2010, 2011;) and newborn infants (Buffler et al. 2006; Cao et al. 2010) but without indications of adverse changes in thyroid hormone levels or thyroid function.

The proposed acceptable perchlorate drinking water level of 620 µg/L differs from the USEPA, Cal EPA, and Mass DEP values of 2-15 µg/L because of the selection of subclinical hypothyroidism as the critical endpoint, rather than inhibition of thyroidal iodide uptake, and because of the relatively small contribution that dietary perchlorate likely makes to the allowable daily dose. The proposed value is preferable to the existing regulatory values because it takes into account non-adverse compensatory mechanisms of thyroid biology, is based on observations of chronic exposure, and protects against an adverse, versus non-adverse, effect.

Appendix A

A.1 Thyroid Biology and Function

Thyroid hormones leave the thyroid, circulate throughout the bloodstream, and enter and interact with organ systems throughout the body. Thyroid hormones are thyroxine (T_4) and triiodothyronine (T_3). Thyroxine is produced in the thyroid and then, with assistance of specific enzymes produced in the liver, convert to T_3. The thyroid uses specific proteins (called sodium-iodide symporters, or NIS) found on the surface of thyroid cells (thyroid follicles) to actively take iodine from the blood. The NIS molecules are the targets of perchlorate, with inhibition of iodide uptake demonstrated in short-term volunteer data (Greer et al., 2002) or long-term therapeutic use (discussed below). Other proteins within the thyroid follicles, along with a hormone from the pituitary gland (thyrotropin, or TSH), integrates the iodine into the formation of T_3 and T_4 molecules. In humans, the thyroid can store significant quantities of T_3 and T_4 in the thyroid cells.

In the cells of the body, T_3 is the active thyroid hormone that interacts with specific molecules in the cell, including portions of DNA, to turn on and off processes that initiate, increase, or decrease growth, development, and energy metabolism. T_4 has little, if any, biological function itself; it is at the ready when needed to be transformed within the cells into T_3 by the removal of one iodine atom. The liberated iodine atom re-enters the circulation where it can be taken back up into the thyroid and re-cycled into new T_3 or T_4, or it may be eliminated in the urine or, to a lesser extent, the saliva and breast milk. Iodine has no other known function in the human body.

In humans and other mammals, most of the thyroid hormone in the blood is in the form of T_4. Further, over 99% of T_4 and T_3 in human blood is bound to specific proteins to act as a ready source of thyroid hormone. As free, unbound T_3 and T_4 are taken from the circulation into body tissues, it is replaced by release of bound hormone. Thus, the body maintains a constant, low level of free T_3 and T_4 in the blood. This capability of healthy humans to maintain a ready supply of thyroid hormone bound in the blood as well as stored in the thyroid itself is not present in laboratory rodents. In rats, the thyroid is constantly stimulated to maintain adequate T_3 and T_4 levels in the circulation. Thus, rats are more susceptible than humans to effects arising from subtle changes in thyroid function and thyroid hormone levels. This difference between species is important when comparing the effects of perchlorate, or any other thyroid-acting agent, in humans and laboratory animals, as is discussed below in greater detail.

Mechanisms are at work in the human body to precisely maintain adequate levels of thyroid hormone in the blood as needs change. The pituitary gland located in the brain can stimulate the thyroid to increase production of thyroid hormone should blood levels of T_4 decrease. Falling T_4 levels in the blood signal the hypothalamus, a specialized region of the brain, to secrete a hormone, TRH, which signals the pituitary to begin secretion of TSH, which stimulates

a number of functions in the thyroid, including increasing the capacity for iodine uptake (through increasing the number of NIS molecules on the thyroid cell surfaces), increasing the production of T_3 and T_4, and increasing production of special proteins that bind T_4 in the blood. Adequate blood T_4 levels signal the hypothalamus and pituitary gland to stop production of TRH and TSH, respectively, which halts the stimulation of the thyroid. This tightly controlled set of feedback and feed-forward mechanisms is known collectively as the hypothalamus-pituitary-thyroid axis.

If conditions occur such that T_4 levels in the blood are too low to maintain proper regulation of growth, development, or metabolism, a medical condition known as hypothyroidism results. Hypothyroidism has numerous causes, including autoimmune thyroid disease, congenital abnormalities of thyroid or pituitary function, treatment with iodine-containing drugs or radiographic contrast agents, or iodine deficiency in the diet. Hypothyroidism can be further graded as subclinical, mild, or overt indicated by slight, moderate, or high levels of TSH in blood and, for mild or overt cases, low blood T_4 levels (Ross, 2005).

A.2 Toxicity Data for Perchlorate

According to the animal and human data discussed below, perchlorate at high doses inhibits the uptake of iodine by NIS proteins on the surface of thyroid follicle cells, thereby, inhibiting the transport of iodine into the thyroid cell. However, the magnitude and duration of reduced iodide uptake into the thyroid must be high enough to overcome compensatory mechanisms that act to maintain homeostatic control to sustain normal thyroid function. One of the ways that the hypothalamus-pituitary-thyroid axis compensates for reduced thyroid uptake is to stimulate an increase in the number of NIS proteins, resulting in more entry points for iodine and reducing the inhibitory effect of perchlorate. Studies in humans have shown that, while perchlorate exposure can result in inhibition of iodide uptake in the short term (Greer et al., 2002), there are transient and adaptive homeostatic mechanisms to offset in humans increases in iodine uptake (Braverman et al., 2004, 2006). This capability can be overwhelmed (as in the case of therapeutic uses of high doses of perchlorate), but at environmental levels of perchlorate exposure, decreased T_4 in the blood does not necessarily follow inhibition of iodide uptake into the thyroid.

The scientific literature for perchlorate toxicology includes many studies in laboratory animals and humans, which are summarized below. Human studies are preferred to determine the dose-response of any chemical. Data from animal studies in the appropriate species should be reviewed as well, bearing in mind the physiological differences between species. As is discussed below, perchlorate interacts similarly with the NIS molecules in human and animal thyroid cells, but the resulting changes in available iodide and resulting levels of thyroid hormone in the circulation are very different between laboratory rodents and humans.

A.2.1 Summary of Human Data

A.2.1.1 Clinical Uses for Perchlorate in the Treatment of Hyperthyroidism

In the 1950s and 1960s in patients with hyperthyroidism, potassium perchlorate was administered to inhibit thyroid iodide uptake, thus reducing the production of T_4 and T_3. Administration of potassium perchlorate was typically at doses ranging from 400 to 2000 mg/day for several weeks or months disease (Leung et al., 2010). Few side effects were noted in these

ED_005043_00062728-00054

patients, with the frequency of side effects reported increasing with increasing dose. However, because of the observation of some side effects and the development of better anti-thyroid drugs, the use of perchlorate to treat hyperthyroidism ceased by the late 1960s.

Although not used as frequently, perchlorate is still used today diagnostically to detect defects in the synthesis of thyroid hormones (NRC 2005). It is also used specifically to treat hyperthyroidism resulting from the administration of the anti-arrhythmic drug, amiodarone. While perchlorate continues to be used for these specific applications, the Food and Drug Administration does not recognize perchlorate as a pharmaceutical for the treatment of endocrine or metabolic disorders (NRC 2005).

A.2.1.2 Occupational Studies

Several occupational studies have been conducted to evaluate thyroid function in workers following long-term exposure to ammonium perchlorate (Gibbs et al. 1998; Lamm et al. 1999; Braverman et al. 2005). Regardless of the characterization of exposure in these cohorts (estimated daily doses approximately 0.3 mg/kg/day), no significant association between estimated exposure to perchlorate and alterations in any of thyroid hormone or TSH measures was reported. In the Gibbs et al. (1998) study, only duration of shift was related to changes in TSH concentrations, with this observation possibly being associated with an increase in serum TSH concentrations expected for workers' changes in the day/night cycle.

The only significant change in an endpoint related to thyroid function reported in any of the occupational studies, was a significant decrease in thyroid radioactive iodine uptake (RAIU) reported in workers following three 12-hour shifts compared to pre-exposure measurements (Braverman et al., 2004). However, serum TSH, serum thyroglobulin (Tg) (a protein essential for thyroid hormone formation) and thyroid volume were not affected. In addition, the RAIU measured in workers during exposure, while lower than preshift values, was comparable to those of community controls. These findings indicated a compensatory response to inhibition of iodide uptake occurring early on in every 3-day work shift, but not result in adaptive changes seen in adults that would result in the development of hypothyroidism or goiter.

A.2.1.3 Ecological Epidemiology Studies

Ecological epidemiology studies have been conducted examining possible associations between environmental exposure to perchlorate in drinking water (4-120 µg/L) and various effects, including thyroid function, thyroid disease, and cancer in children (including low-birth-weight or preterm newborns and offspring of mothers who were hypothyroid or had iodide deficiency during gestation) and adults (Rockette and Arena, 1983; Li et al., 2000a, 2000b, 2001; Morgan and Cassidy, 2002; Lamm and Doemland, 1999; Brechner et al., 2000; Crump et al., 2000; Schwartz et al., 2001; Chang et al., 2003; Kelsh et al., 2003; Lamm, 2003; Buffler et al., 2004, as cited by NRC 2005). NRC (2005) noted that while ecologic study design may be limited in their ability to establish cause-and-effect of toxicity, the association, or lack thereof, of exposure and toxic endpoint can be informative when combined with other data on the biology of the thyroid gland and experimental studies of the effects of acute exposure to perchlorate. The NRC Committee concluded that the available epidemiologic data did not indicate a causal association between perchlorate exposure and congenital hypothyroidism, perturbations of

ED_005043_00062728-00055

thyroid hormone and TSH production in normal newborns, or thyroid diseases or hypothyroidism in normal adults. NRC (2005) further determined that there was inadequate evidence to motivate the conduct of a study of possible associations between perchlorate exposure and neurodevelopmental outcomes in children (e.g., autism, ADHD) or thyroid cancer in adults.

Ecological epidemiological studies published since the NRC (2005) assessment have focused on evaluating the potential association between perchlorate exposure and indicators of thyroid function in pregnant women (Pearce et al. 2010, 2011; Tellez et al. 2005) and newborn infants (Buffler et al. 2006; Cao et al. 2010). In the Pearce et al. (2010) study, subjects were a subset of pregnant women involved in the Controlled Antenatal Thyroid Screening Study (CATS). This prospective study was designed to determine whether L-T_4 for hypothyroid or hypothyroxemic pregnant women during pregnancy improves child development. In 2002, a total of 22,000 women with single pregnancies at less than 16 weeks were enrolled in this program. For the subset 1002 women considered by Pearce et al. (2010), urinary iodine, thiocyanate, and perchlorate and serum TSH, free T_4 and thyroperoxidase antibodies (an indicator of thyroid function) were measured. Urine perchlorate was detectable in all women studied, with a median concentration of 2-5 µg/L, depending upon location (Turin, Italy versus Cardiff, Wales). No associations between urine perchlorate concentrations and serum TSH or free T_4 were observed. In addition, perchlorate in urine was not a predictor of free T_4 or TSH in blood. The authors concluded that low-level perchlorate exposure is ubiquitous, but it is not associated with alterations in thyroid function among iodine-deficient women in the first trimester of pregnancy. They also noted that their sample is the largest to date in women with low urinary iodine levels, all of whom were pregnant, and that it is in contrast to a smaller study conducted in the United States by Blount et al. (2006). Pearce et al. (2011) reported similar results in a study conducted in smaller groups of pregnant women from Los Angeles, California (N=134) and Cordoba, Argentina (N=107). In nonpregnant women with similar urine iodine (less than 100 µg/L) and perchlorate concentrations as those reported by Pearce et al. (2010), Blount et al. (2006) reported increases in serum TSH and lower serum T_4 concentrations. However, a re-analysis of the same data by Pearce et al. (2007) in which urinary perchlorate levels were more appropriately corrected for creatinine excretion (reducing the effect of variable urine volume among subjects), did not find an association urinary perchlorate and T_4 and TSH levels in blood.

Tellez et al. (2005) conducted a longitudinal epidemiological study among pregnant women in three areas of Chile with drinking water concentrations of perchlorate that varied from 0.5 to 114 µg/L. It was the same areas evaluated by Crump et al. (2000) to evaluate potential effects in school children from exposure to perchlorate. No increases in thyroglobulin (Tg) or TSH or decreases in free T_4 were observed among women in early pregnancy (approximately 16 weeks) or late pregnancy (approximately 32 weeks). In addition, no significant changes in the thyroid hormone indicators were seen in newborns related to perchlorate drinking water concentration. These studies have been criticized for focusing on a population having higher iodine ingestion than in the U.S. Further analysis, however, by Van Landingham and Gibbs (2008) of only iodide-deficient women within these data found no association between urinary perchlorate and T_4 or TSH levels.

In ecologic studies focused on the evaluation of indicators of thyroid function in infants (Cao et al. 2010; Buffler et al. 2006), Cao et al. (2010) reported a weak but significant association

between higher urinary perchlorate (expressed as log perchlorate in µg/g creatinine) and higher TSH concentrations in infants with lower urinary iodine (<100 µg/L) in children enrolled in the Study of Estrogen Activity and Development (Cao et al. 2009). This study design was partly cross-sectional (offering a "snapshot" of data in time) and partly longitudinal (following the subjects over time), since some children were evaluated at multiple visits. Blood and urinary TSH and T_4 were measured in each child at each visit.

The Buffler et al. (2006) study included 342,257 newborns screened by the California Newborn Screening program in 1998, whose mothers resided in communities in which ground water was tested for perchlorate in 1997 or 1998. The endpoints of interest for evaluation in the study were the presence of clinically-diagnosed primary congenital hypothyroidism (PCH) and serum TSH concentrations in the newborns. In evaluating any correlation TSH and perchlorate ground water concentrations, the authors considered the time in which perchlorate was measured in the infant after birth as a critical factor in evaluating the results, because a normal postnatal surge of TSH is present within the first 24 hours after birth that could impact the interpretation of the results. Therefore, only infants whose TSH was measured at a time point greater than or equal to 24 hours of age was considered. Calculations were controlled for confounding factors such as sex, ethnicity, birth weight, and multiple birth status. The study authors reported no association between estimated average perchlorate concentrations of greater than 5 µg/L in drinking water supplies and the prevalence of clinically diagnosed PCH or high TSH concentrations.

A.2.1.4 Clinical Volunteer Studies

Several clinical studies have been conducted to evaluate the potential effects of potassium perchlorate in healthy subjects, with exposure duration ranging from 2 weeks to 6 months (Brabant et al. 1992; Lawrence et al. 2000, 2001; Greer et al. 2002; Braverman et al. 2006). Doses in these studies ranged from 0.007 to 0.5 mg/kg/day in drinking water. Endpoints considered in these studies included measurements of serum T_4, T_3, and TSH concentrations, as well as evaluation of changes in RAIU.

No statistically significant changes in thyroid hormone levels (T_4, T_3, TSH levels in blood) that would indicate an impact on thyroid function leading to hypothyroidism were reported in any of these clinical studies. Some authors noted slight decreases in TSH (Brabant et al. 1992; Greer et al. 2002), which is inconsistent with hypothyroidism, in which a significant increase in TSH would be expected. Significant transient decreases in 24-hour RAIU were noted in clinical studies in which perchlorate was administered for 2 weeks, with a return to baseline levels following cessation of exposure (Lawrence et al. 2000, 2001; Greer et al. 2002). However, most importantly, in the study with the longest duration of exposure (6 months) (Braverman et al. 2006), no statistically significant effect on 24-hour RAIU was observed. While this study is limited by small sample size (N=13, 9 treated and 4 placebo controls), it does provide information on levels of perchlorate ingestion (up to approximately 0.04 mg/kg/day) to which healthy individuals can be exposed for a longer-term duration with no impact on indices of thyroid function.

USEPA (2005) based the current Reference Dose (RfD) on changes in RAIU uptake reported in the 2week clinical study by Greer et al. (2002), which provided evidence that there were no

ED_005043_00062728-00057

other significant changes in T_4, T_3 and TSH concentrations. USEPA (2005) also noted that chronic exposure will have no greater effect than that resulting from short term exposure; lack of the precursor event of inhibition of iodide uptake will result in no changes in thyroid function in the short or long term. In fact, prolonged exposure will actually have less effect because of the capacity of the hypothalamus-pituitary-thyroid axis to compensate for iodide deficiency by increasing iodide uptake, as seen in the Braverman et al. (2005) study of perchlorate workers. USEPA (2005) further noted that if some inhibition of iodide uptake by the thyroid did occur at the minimal dose at the point of departure, data from humans indicated that longer exposures were not likely to result in a greater or more severe response.

A.2.2 Summary of Laboratory Animal Data

The following sections include a brief review of the animal studies pertaining to perchlorate health effects. The studies evaluated for these sections were those included in the NRC (2005), *Health Implications of Perchlorate Ingestion* report and those studies, published post-2005 located in a literature review. The information summarized in this section includes results of rodent studies that look for changes in thyroid hormone levels, reproductive and developmental effects, brain changes, and cancer.

A.2.2.1 Effects on Thyroid Hormone Levels

An evaluation of the effects of perchlorate on thyroid hormones and thyroid histopathology was conducted in pregnant rats and their offspring (Argus, 2001; York et al., 2001a). Argus (2001) gave pregnant rats perchlorate in drinking water at doses ranging from 0.01 to 30 mg/kg/day throughout pregnancy (gestation) and lactation. Argus (2001) reported dose-related increases in serum TSH in the mothers (dams), fetuses, and pups at ≥0.01 mg/kg/day, decreases in T_4 at ≥0.01 mg/kg/day, and decreases in T_3 at 30 mg/kg/day. The NRC (2005) summary of the Argus (2001) study did not indicate whether statistical analyses used individual pups or litters as the experimental unit for comparison of thyroid hormone levels. Similar significant decreases in T_4 were also reported in pregnant rabbits at doses ≥30/mg/kg/day (York et al. 2001b).

Studies in non-pregnant rats or pregnant prairie voles (James-Walke et al., 2006) and deer mice (Smith et al., 2006) did not report changes in thyroid hormone levels. Drinking water concentrations that resulted in an estimated intake of perchlorate of 0.05 or 0.4 mg/kg/day for 21 days did not produce significant changes in blood T_4 hormone levels in female rats (James-Walke et al. 2006). Similar results were reported in prairie voles and deer mice given perchlorate at concentrations resulting in 0.7-1.1 mg/kg/day in either food or drinking water (Smith et al. 2006).

Two studies in rats have investigated the effects of iodide deficiency on the thyroidal effects of perchlorate exposure(Paulus et al., 2007; Wu et al., 2010). Rats fed iodine-deficient diets absorbed greater amounts of iodide into the thyroid at about twice the rate of rats fed normal diets (Paulus et al. 2007). Following administration of perchlorate at concentrations of 1.1-28 µg/L in drinking water (0.1-3 mg/kg/day), the normal-diet rats showed significant inhibition of thyroidal iodide uptake at all doses, while the iodide-deficient rats had significant inhibition of iodide uptake only at 28 µg/L. These findings indicated that iodide-deficiency in rats stimulates

ED_005043_00062728-00058

a compensatory increase in iodide uptake capacity that offsets perchlorate-induced inhibition up to a certain level.

Wu et al. (2010 reported similar reductions in T_4 and increases in TSH in treated and in non-treated iodine-deficient rats. They also reported differences in genetic expression of two enzymes and proteins involved with T_3 and T_4 production in the thyroid at different doses, but not in the iodine-deficient animals. These study authors speculated that, in addition to iodide uptake inhibition, perchlorate may affect thyroid hormone balance by another mechanism. However, they offered no explanation as to why the differences in genetic expression markers were not expressed at the same levels that affected T_4 and TSH, or why iodine deficiency resulted in similar changes to T_4 and TSH if there were, in fact, another mechanism responsible to effects associated with perchlorate exposure in laboratory rats.

McLanahan et al. (2009) used a mathematical computer model to investigate the influence of iodine uptake inhibition on thyroid hormone levels. Their results corroborated the conclusions of Wu et al. (2010), suggesting that the effects of perchlorate in the thyroid may to occur through more thanone mode of action, by blocking iodide transport as well as interacting in some way with thyroid hormone production and release.

A.2.2.2 Effects on Brain Structure

Argus (1998) reported an increase in thickness of specific brain tissues of rat pups born to dams exposed 0.1-10 mg/kg/day perchlorate in drinking water throughout pregnancy. Argus (2001) extended their 1998 analysis by performing brain measurements on additional groups of rats using a higher dose (30 mg/kg/day) and additional sampling times during pregnancy. Again, they reported significant increases in thickness of brain tissues, but could not demonstrate an increase in effect as doses increased.

Concerns have been raised about the Argus (1998, 2001) studies from outside reviewers (Harry, 2001; Wahlsten, 2002; Elberger, 2003; Gellar, 2003). In general, the concerns were: 1) The systematic differences in how brain samples were measured between treatment groups; 2) the lack of a dose-response relationship, and 3) concerns about the biologic plausibility of the changes that were reported. Based on their review of Argus (1998, 2001), NRC (2005) concluded that the data from Argus (1998, 2001) were inadequate to identify a causal relationship between maternal perchlorate exposure and pup neurodevelopmental abnormalities.

A.2.2.3 Effects on Neurobehavior

Previous research has suggested that changes in thyroid hormone levels occurring during fetal development could interfere with normal brain development, including changes in the brain areas that may be involved in motor coordination (Chan and Kilby, 2000). The Argus (1998) study discussed above included a battery of behavioral tests performed on the offspring of rats exposed to perchlorate in drinking water during pregnancy. Significant changes were not observed during several standard tests following doses of 0.1 to 3 mg/kg/day, the highest dose tested. However, Argus (1998), but not Bekkedal et al. (2000), observed significant changes in locomotor activity in litters of rat pups born to dams exposed to 10 mg/kg/day.

The effects of perchlorate on developmental neurotoxicity reported by Argus (1998) were not observed in a longer exposure study by York et al. (2005a, 2005b). Offspring from female rats exposed to up to 30 mg/kg/day perchlorate from 2 weeks prior to mating through day 10 of lactation exhibited no changes in a variety of motor activity variables, suggesting that perchlorate exposure in the womb and through lactation did not significantly affect the development of simple muscle movements in pups (York et al., 2005b).

Exposure to perchlorate during gestation did not impair behavioral test endpoints in the male offspring of females exposed to drinking water concentrations up to 1000 ppm (Gilbert and Sui, 2008). Significant reductions in electrophysiological assessments (suggesting adverse effects in the hippocampal region of the developing brain) were reported for the offspring at all dose levels. However, a consistent dose-response relationship was not observed, and the lack of behavioral changes (sensitive to deficiencies in the brain hippocampus) did not comport with measured electrophysiological changes (Mavis and DeSesso, 2009).

To evaluate the thyroid hormone action in the brain, Sharlin et al. (2010) measured gene expression, indicators of thyroid hormone action in the brain, in the offspring of pregnant rats administered methimazole and potassium perchlorate to induce hyperthyroidism during gestation. There was a significant decrease in blood T_4 levels and body weight in young pups. However, the findings did not support the notion of the developing rat brain being capable of compensating for low T_4 levels.

A.2.2.4 Effects on Reproductive and/or Developmental Function

Studies in several species examined the effect of perchlorate exposure in the diet or drinking water on reproduction. No changes in reproductive endpoints were see in rats (York et al. (2005a, 2005b), deer mice or prairie voles (Smith et al., 2006), or rabbits (York et al., 2001b).

A.2.2.5 Thyroid Gland Tumors

Cancer and noncancer effects on the thyroid gland have been reported in both mice and rats following long term exposures to high doses of perchlorate (Kessler and Kruskemper, 1966; Pajer and Kalisnik, 1991; Fernandez-Rodriguez, 1991). Thyroid cellular changes and nodules were reported in female rats administered 1% perchlorate in drinking water for up to 12 months (Fernandez-Rodriguez, 1991). In rats, daily drinking water doses of 1,339 mg/kg/day for a lifetime produced benign thyroid tumors in 4 of 11 treated rats (Kessler and Kruskemper, 1966), while thyroid carcinomas were observed in 5 of 6 mice exposed to 2,147 mg/kg/day in drinking water for 46 weeks (Pajer and Kalisnik, 1991). In both studies of mice and rats, no tumors were observed in the control animals.

Thyroid benign tumors were reported in male rats in a two-generation reproductive study (Argus 1999). In this study, male rats in the first generation were given perchlorate in drinking water from 70 days before mating until age of 24-25 weeks. The male offspring were exposed to the same duration of dosing, with additional exposure through pregnancy and lactation. The microscopic tissue changes, which were re-evaluated by USEPA (Wolf, 2000; USEPA, 2002), reported that two first-generation males in the 30 mg/kg/day group and one second-generation male control rat had benign thyroid tumors. Both the USEPA (2002) and the NRC (2005) concluded that while the thyroid tumors seen in the treated male rats were not statistically

ED_005043_00062728-00060

significant, the appearance of tumors as early as week 19 indicated that they were likely treatment-related.

A.3 Differences in Animal and Human Perchlorate Toxicokinetics

The function of the thyroid in rats and humans is qualitatively similar; however, some differences between the two species in chemical binding of perchlorate to thyroid proteins in the blood and rates of clearance from the body present important quantitative differences (NRC 2005). The principal protein that binds T_4 in human, thyroxine-binding globulin (TBG) is not present in rats. Most of the T_4 in rats is bound to two other bold proteins: albumin and transthyretin, which have a T_4 binding affinity ("tightness of binding") of about 100 times less than TBG in humans. Therefore, T_4 is cleared from the body more quickly in rats than in humans, requiring a higher production rate of T_4 per unit body weight. In the liver, rats and humans join T_4 to a specific carbohydrate molecule to form a compound class (glucuronide conjugate) that may then be eliminated in the bile. This mechanism is used by the body to promote elimination of many chemicals. However, about 50% of T_4 in the rat gets eliminated in the bile, compared to only 10-15% in humans.

The lower binding capacity for T_4 blood as well as the much smaller thyroidal storage capacity of T_3 and T_4 in rats, compared to human, requires that rats produced thyroid hormone on a continual basis, with almost constant stimulation by TSH. In studies of perchlorate-induced iodide uptake inhibition, rats exhibited compensation for reduced iodide availability within 5 days (York et al., 2002) of exposure, while human volunteers did not compensate by 14 days of drinking water exposure, even though iodide uptake was inhibited by as much as 67% (Greer at al., 2002). Longer durations of perchlorate exposure in human volunteers (6 months) (Braverman et al., 2006) and perchlorate workers (≥1.7 years) (Braverman et al., 2004) did result in evidence for compensatory mechanisms by increasing the thyroid's capacity to take up iodide from the blood.

Changes in blood concentrations of T_3, T_4, and TSH following perchlorate exposure are different in rats and humans. Following 14 days of perchlorate exposure in rats, Siglin et al. (2000) reported significant decreases in T_3 and T_4 levels, and significant increases in TSH. However, no significant changes in TSH, T_3, or T_4 have been reported in adult humans exposed to up to 0.5 mg/kg/day perchlorate for 14 days (Lawrence et al. 2000; Greer et al. 2002), six months (Braverman et al., 2004), or ≥1.7 years (Lamm et al., 1999; Braverman et al., 2004).

There are also differences between rats and humans in pituitary-thyroid function during pregnancy and in the fetal development of the thyroid. In humans, blood T_3 and T_4 levels increase during pregnancy and remain elevated through most of pregnancy (Glinoer 1997). In rats, blood T_4 levels significantly decrease during gestation days 17-22 (4 days leading up to birth), compared to non-pregnant rats (Fukuda et al. 1980; Calvo et al. 1990; Versloot et al. 1994). These differences are mostly related to the lack of TBG in rats. At birth, thyroid function in the rat is relatively immature, and equivalent to that of a third-trimester human fetus. In humans, thyroid function in the womb supported by maternal thyroid hormones, while T_4 and T_3 levels in newborn rats don't increase until 5 to 15 days after birth due to an increase in a blood thyroid hormone binding protein (Obregon et al. 1991).

Computer models capable of simulating perchlorate toxicokinetics in rats and humans, termed physiologically based pharmacokinetic (PBPK) models, have been developed (Clewell et al., 2007) and evaluated by USEPA (2009). These models allow for prediction of perchlorate doses to various tissues, including transfer of perchlorate and iodide to the developing fetus and breastfeeding infant, under a variety of exposure scenarios. However, the models were not designed to predict compensation of the hypothalamus-pituitary-thyroid axis for inhibited RAIU or the effect that these mechanism have on thyroid hormone levels. Because of this, the models are limited in their application to simulate and compare chronic doses and effects (or lack) reported in occupational or epidemiological studies.

A.4 Relevance of Animal Data to Human Risk

With regard to non-cancer and cancer effects of perchlorate, the rodent data should not be used in the quantitative estimation of human risk. Comparison of differences between the species of the physiology of the of the thyroid gland, capacity of thyroid hormone binding in blood, rate of elimination from the system, and onset of hormone production and availability of maternal hormones in the developing offspring indicate that rats are clearly more sensitive than humans to perturbations of iodide uptake into the thyroid. Because the rat thyroid is under near-constant stimulation by the pituitary gland to maintain blood T_4 levels, not having the reserve of thyroid hormone in the thyroid and the blood found in humans, additional chemical-induced stresses on the hypothalamus-pituitary-thyroid axis are likelihood to result in adverse effects not seen in humans or at much lower doses and shorter exposure durations (USEPA, 1998).

For thyroid carcinogenicity, an International Agency for Research on Cancer (IARC) working group stated that chemicals found to induce thyroid tumors in rodents by interfering with thyroid hormone balance can, with some exceptions (i.e., sulfonamide drugs), also interfere with human thyroid balance if given long enough at sufficiently high doses. However, these agents can be assumed not to cause cancer in humans at exposure levels that do not lead to changes in human thyroid hormone balance (IARC, 2001). This was echoed in a USEPA science policy document (1989) and by NRC (2005), stating that humans may not be as sensitive quantitatively to thyroid cancer development of thyroid-pituitary disruption as are rodents.

Re: Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate, Docket No. EPA-HQ-OW-2016-0438-0001 (81 Federal Register 67350, September 30, 2016)

Dear Mr. Perkinson:

The American Chemistry Council[1] (ACC) is pleased to submit these comments on EPA's proposed Peer Review Materials to Inform the Safe Drinking Water Act Decision Making on Perchlorate,[2] specifically the draft Biologically Based Dose-Response (BBDR) Model and the accompanying draft model report titled "Biologically Based Dose Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses."[3] ACC supports the use of the best available science to support regulatory actions for perchlorate, one of the most well-studied drinking water contaminants[4] with detailed information on the mode of action, dose-response, and health effects.

[1] ACC represents the leading companies engaged in the business of chemistry. ACC members apply the science of chemistry to make innovative products and services that make people's lives better, healthier and safer. ACC is committed to improved environmental, health and safety performance through Responsible Care®, common sense advocacy designed to address major public policy issues, and health and environmental research and product testing. The business of chemistry is a $797 billion enterprise and a key element of the nation's economy. It is the largest exporting sector in the U.S., accounting for 14 percent of U.S. exports. Chemistry companies are among the largest investors in research and development, investing $93 billion in 2015.

Support for Modeling Approach
In 2013, EPA's Scientific Advisory Board (SAB) panel recommended that EPA develop a physiologically-based pharmacokinetic/pharmacodynamics (PBPK/PD) modeling approach to support the development of a National Primary Drinking Water Regulation (NPDWR) for perchlorate.[5] ACC continues to support EPA's commitment to derive a maximum contaminant level goal (MCLG) for perchlorate using BBDR modeling and mode of action information rather than the default MCLG ("algebraic") approach using the reference dose (RfD) and specific chemical exposure parameters and associated assumptions.[6] In response to SAB, EPA, working with U.S. Food and Drug Administration (FDA) scientists, developed a draft BBDR (also called PBPK) model that integrates PBPK/PD models for perchlorate and iodide with BBDR models for thyroid hormones. The integrated model predicts the effect of perchlorate on thyroid hormone levels in lactating mothers, as well in formula- and breast-fed infants.

Sensitive Subpopulations
While EPA's focus on one or more of these sensitive populations is appropriate, its potential selection of a nutritionally iodine-deficient subpopulation of these sensitive populations as the basis of its BBDR modeling—and subsequent development of an NPDWR—would be unprecedented.

> **Recommendation – At a minimum, EPA should acknowledge both the exceptionally conservative nature of the approach and that its use should correspond with a reduction in or elimination of the use of uncertainty factors in the subsequent development of an MCLG.**

Hypothyroxinemia and the Critical Effect
The integrated draft model focuses on "hypothyroxinemia"—a condition that occurs when free thyroxine (fT4) levels are decreased while thyroid-stimulating hormone (TSH) levels are maintained in the normal range—as an indicator of potential adverse health effects resulting from exposure to perchlorate. Hypothyroxinemia is considered a more sensitive and therefore better "indicator of the potential adverse health effects than the more pronounced decreases in thyroid function associated with hypothyroidism".[7] However, the selection of hypothyroxinemia is not consistent with EPA's definition of "critical effect"—that is, the first adverse effect or its known precursor [singular] that occurs as dose rate increases.[8] There is no clinical definition of hypothyroxinemia and it is not characterized as adverse or treated by medical authorities. Rather, its mode of action is unknown and might be adaptive or compensatory—neither of which is adverse. Also, no clear fT4

ED_005043_00062728-00065

reference range exists in the literature to define it. According to the National Research Council's seminal review of perchlorate[9] and EPA's definition, the critical effect is hypothyroidism or its immediate precursor, thyroid hypertrophy or hyperplasia.

> **Recommendation – EPA should provide additional justification for using hypothyroxinemia as the critical endpoint for determining adverse effects associated with perchlorate exposure.**

Model Parameters and Validation

Although the proposed BBDR model uses multiple physiological parameters (e.g., body weight over time, fractional blood flow) to set the life-stage-specific values for iodide/thyroid hormones and perchlorate, EPA's draft model report notes that "many of the iodide/thyroid hormone and perchlorate parameters where [sic] not available for specific life-stages, and so were extrapolated from other life-stages or in-vitro data".[10] Therefore, assumptions have been made to set the parameters for the model that might weaken the predictive outcomes of the draft model.

> **Recommendation – EPA should carefully consider any deviations between its draft model output and observations from available prospective epidemiology studies such as Téllez et al. (2005).[11]**

Moreover, if appropriate data are not available to validate the model (i.e., "back-check" modeling results with observations) additional data will need to be collected from biomonitoring studies or generated in animals before the model can be considered to accurately predict outcomes resulting from exposure to perchlorate in drinking water.

The proposed BBDR model does not account for other chemicals besides perchlorate that also inhibit the sodium iodide symporter (NIS) that transports iodine into the thyroid,[12] such as nitrate and thiocyanate that form part of a healthy diet and that occur in background levels far exceeding perchlorate. The draft model also does not account for well-understood compensatory (homeostatic) control mechanisms that mobilize stores of iodine from the mother in the infant's thyroid.[13, 14] These stores compensate for short-term fluctuations in iodide uptake via NIS upregulation. If such upregulation is not addressed in the model, the results may contribute to an unduly conservative RfD/MCLG.

Peer Review

ACC commends EPA for forming two separate peer review panels to evaluate (1) the draft BBR model and draft model report, and (2) its application to develop a drinking water standard for perchlorate.[15] However, we still have concerns with several areas of the planned peer review process.

First, the companion Federal Register notice of September 30, 2016,[16] notes that EPA's contractor, Versar, Inc., will "provide a report to EPA summarizing the peer reviewer's [sic] evaluation of the scientific and technical merit of the draft model and draft report…" It is not clear that Versar, Inc. has the necessary expertise to accurately summarize the science and science policy questions and issues associated with the highly complex BBDR model or to accurately reflect the issues, conclusions, and recommendations of the peer review panel.

> **Recommendation – Given the complexity of the draft BBDR model and the 2013 SAB Perchlorate Panel's call for transparency, the planned peer review panel, not the contractor, should draft its own report to EPA.**

Second, the Federal Register notice also states that "Versar, Inc., will provide reviewers with a summary of public comments on the draft BBDR model and report submitted to EPA's docket..." Again, owing both to the complexity of the model and to adhere to the SAB Perchlorate Panel's call for transparency:

> **Recommendation – All public comments that are technical in nature should be provided directly to the peer review panel members in entirety—not just as a summary.**

Lastly, and consistent with the previous SAB panel process:

> **Recommendation – EPA's peer review process should result in a consensus-driven report rather than simply reflect the individual perspectives of the panel members.**

ACC appreciates consideration of these comments by EPA and the peer review panels. If you have any questions, please feel free to contact me by phone at 202-249-6709 or via email at judith_nordgren@americanchemistry.com.

RE: Comments on the draft Biologically Based Dose-Response (BBDR) model for Perchlorate (81 FR 67350; EPA-HQ-OW-2016-0438)

Dear Mr. Beauvais:

The American Water Works Association (AWWA) appreciates the opportunity to review and comment on the draft Biologically Based Dose-Response (BBDR) model for Perchlorate (81 FR 67350; EPA-HQ-OW-2016-0438). Given the complexity of the model and originality of the approach, we believe that a 90 day comment period would have provided the public with a more reasonable opportunity for review and comment, but we appreciate the 11-day extension provided by the agency.

We also recognize and support EPA's work to address the recommendations made by the Science Advisory Board in 2013. In that regard, the following comments note several areas that we believe the peer review panel should evaluate closely and recommend actions that EPA can take to enhance the models scientific integrity. These comments are focused EPA's responsiveness to the model revisions recommended by the SAB and keys assumptions that the peer review panel should consider closly is assessing the efficacy of the model.

We recognize and support EPA's efforts to address the recommendations made by the Science Advisory Board in 2013. In that regard, the following comments note several areas that the peer review panel should evaluate closely. These include recommendations to enhance the model's scientific integrity, and comments on both EPA's responsiveness to the model revisions recommended by the SAB and on key assumptions in assessing the efficacy of the model.

In brief, our review found several assumptions that limit or constrain the models ability to reasonably generate biologically or clinically realistic outputs, especially when compared to prospective epidemiology studies. In addition, EPA's choice of critical effect requires careful review to ensure that EPA's own criteria are satisfied appropriately, especially since hypothyroxinemia is difficult to portray as a clinically relevant effect. Finally, a significant gap in the model is the absence of any consideration for the body's ability to up regulate the production of thyroid sodium-iodine symporter proteins. Such ability, already demonstrated with perchlorate exposure, makes any modeling result that excludes it conservative.

Should you have questions or would like to discuss this matter, please contact me (tmehan@awwa.org) or Kevin Morley (kmorley@awwa.org).

Sincerely,

G. Tracy Mehan, III

Synopsis

The physiologically-based pharmacokinetic/pharmacodynamic (PBPK/PD) model of EPA (2016a) accounts for exposure differences and biological differences across life stages, including sensitive life stages, and is a good start at understanding the complexities of iodine nutrition, perchlorate exposures, and sensitive populations. However, EPA (2016a) will need to carefully explain the designation of thyroid or pituitary hormone changes as critical effects, in contrast to NAS (2005) and EPA's own definitions (EPA, 2016b). EPA will also need to support their assumption of 2.5th to 10th percentile of fT4 as a hypothyroxinemia range, and incorporate symporter up regulation in the model.

Specifically, EPA could select as a point of departure the perchlorate dose associated with a lower 2.5th percentile of fT4 in the chosen sensitive population. If so, EPA will need to support the assumption that this lower 2.5th percentile evokes changes in TSH, which, although not technically the critical effect, may be a reasonable surrogate for thyroid hyperplasia and hypertrophy, which is/are the known precursor to the first adverse effect from perchlorate exposure (NAS, 2005, page 111). Alternatively, EPA could revise the model so that changes in TSH could be explored as the basis for its point of departure (POD). Such TSH changes are closer to the critical effect of perchlorate.

In addition, if EPA selects an iodine-deficient subpopulation as one of the sensitive populations as the basis for its RfD or MCLG, then EPA should acknowledge that this choice is conservative, and further, reduce or forgo an uncertainty factor for within human variability in the development of the RfD or MCLG.

We also highly recommend that EPA carefully consider any deviations between the model output and observations from prospective epidemiology studies, and specifically encourage EPA to carefully review the work of Crump et al. (2000) and Tellez et al. (2005) for applicability to the US. This review would be consistent with one of the conclusions of the NRC (2005, page 69).

Furthermore, we highly recommend that EPA consider how the modeled perchlorate dose response assessment might be modified by up regulation of symporter expression in the perchlorate dose range of interest. If up regulation is occurring, then it needs to be addressed in the model, or if this is not possible, then EPA should acknowledge that the unmodeled up regulation leads to a more conservative RfD or MCLG, all other factors remaining the same.

Finally, and as EPA already knows, from a clinical perspective lactation is associated with iodine uptake in the breast, and, there is a well-documented clinical increase in thyroid hormone requirements during pregnancy. However, colleagues of the University of Cincinnati, College of Medicine are unaware of any clinically increased rate of hypothyroidism in breast-feeding women compared to those choosing to feed their children formula. Thus, pregnancy and its increased thyroid hormone requirements have a far greater impact on the mother than breast-feeding.

ED_005043_00062728-00073

We encourage EPA to further explore the clinical relevance of the breast-feeding maternal population prior to choosing it for any point of departure in developing an RfD or MCLG.

Specific Comments

In the Science Advisory Board (SAB) 2013 review of perchlorate, they concluded that EPA should:

1) **Consider exposure to the following sensitive life stages: the fetuses of hypothyroxinemic pregnant women and infants exposed to perchlorate through either water-based formula or the breast milk of lactating women.**

   Response:

   We agree that protecting these life stages will protect other, less sensitive subgroups in our population. Previous Reference Doses (RfDs) for perchlorate were either based on human adults (NRC, 2005; EPA, 2016c) or children (Strawson et al., 2004a,b,c), with an uncertainty factor for within human variability that varied due to the population chosen (10-fold for NAS & EPA and 3-fold for Strawson et al.). EPA's choice of either fetuses of hypothyroxinemic pregnant women and/or infants exposed to perchlorate through either water-based formula and/or the breast milk of lactating women further refines our understanding of the most sensitive population and can lead to a further reduction in the uncertainty factor for within human variability. EPA has reduced or obviated the need for this factor on a number of occasions when the sensitive human population was known (e.g., Dourson et al., 2001).

   However, while EPA's appropriate focus is on one or more of the sensitive populations above, its potential selection of a nutritionally deficient subgroup as the basis of a revised RfD, specifically, an iodine-deficient subpopulation of one of these sensitive populations may be a first. To our knowledge, EPA has never determined a RfD, Reference Concentration (RfC), or risk specific dose (RSD) on the basis of a nutritionally deficient experimental animal or human population. If EPA selects an iodine-deficient subpopulation of one of these sensitive populations as the basis for its RfD, then it should acknowledge that this choice is conservative, and further consider whether an uncertainty factor for within human variability is needed.

   In the case of perchlorate, US populations traditionally considered to be iodine deficient, such as vegetarians, may not be so, or if so and used as the basis of an RfD, then an uncertainty factor for within human variability may not be needed. For example, Fields et al. (2005) state:

   > Recent risk assessments of environmental perchlorate have been subject to much debate. A particular concern is whether appropriately susceptible sub-populations have been identified. Iodine-deficient

ED_005043_00062728-00074

> pregnant women, especially vegetarians, have been proposed as such a potential susceptible sub-population, but there is no evidence of iodine deficiency in the US population and the adequacy of iodine nutrition has not been studied in US vegetarians. To understand the possibility that US vegetarians might be iodine deficient, we reviewed the prevalence, demography, and lifestyle characteristics of US vegetarians as well as the world literature on iodine nutrition in vegetarians. Our findings indicate that strict vegetarians and vegans, who comprise probably less than 0.1% of the US population, have higher education, higher incomes, and healthier lifestyles than the general population. Field studies indicate that vegetarian diets need not lead to iodine deficiency and vegans may suffer excess iodine intake. It remains uncertain whether there are iodine-deficient vegans or pregnant women in the US. Of more general concern is whether the 10-fold default uncertainty factor is needed for intraspecies (i.e., within human) variability to protect such hypothetical susceptible sub-populations.

In dramatic contrast, iodine deficient populations may not be more sensitive to perchlorate exposures than populations that are iodine replete. This counter-intuitive proposition is supported, for example, by Steinmaus et al. (2016) who show that while the adjusted associations for their **total cohort** were identified between increasing log10 perchlorate and decreasing total thyroxine (T4) [regression coefficient (β) = –0.70; 95% CI: –1.06, –0.34] and decreasing free thyroxine (fT4) (β = –0.053; 95% CI: –0.092, –0.013), these associations were driven entirely by **the high iodine subcohort**. What these data show are that in low iodine situations, perchlorate is not having an effect on thyroid hormone production. A more appropriate conclusion from the Steinmaus et al. (2016) would be that perchlorate does not affect low iodine populations.

What might be happening biologically to support this observation?

One possible explanation may be the up regulation of symporter protein production in low iodine situations, leading thyroid cells to create additional symporter iodine channels. If this occurs in low iodine situations, then the thyroid gland would have more channels available for iodine intake, and perchlorate would have commensurately less effect in iodine uptake inhibition. Unfortunately, Steinmaus et al. (2016) did not measure symporter protein production in their cohort, but EPA's model can be revised to account for this by including a parameter for symporter protein up regulation, as described later in these comments.

Importantly, if EPA assumes that iodine deficiency is a sensitive condition and choses to use this in its modeling, then this choice should be associated with a commensurate reduction in the use of the uncertainty factor for within human variability. A 1-fold factor would be appropriate and consistent with other extant EPA choices of 1-fold for the within human variability uncertainty factor for

ED_005043_00062728-00075

RfDs with equivalent or even less data than what are available for perchlorate (e.g., benzoic acid, fluoride, and manganese) or RfCs (e.g., beryllium) on EPA's Integrated Risk Information System (EPA, 2016d).

2) **Derive the MCLG using a physiologically-based pharmacokinetic/ pharmacodynamic (PBPK/PD) model to account for exposure differences and biological differences across life stages, including sensitive life stages. Specifically, the SAB found that the 'default algebraic approach provides limited ability to address the various exposure and biological factors affecting sensitivity to perchlorate at different life stages. The SAB concluded that, from a scientific standpoint, it would be more appropriate to base the MCLG derivation on the perchlorate mode of action, using PBPK/PD modeling to relate perchlorate concentrations in drinking water to biological effects rather than the default approach.**

Response:

We agree that development of a PBPK/PD model to replace the usual No Observed Adverse Effect Level (NOAEL) and its associated default uncertainty factors is progressive. However, it will be important for EPA to carefully explore its underlying assumptions of critical effect (more about this in later comments), and check its modeling results with observations of thyroid hormone changes, or their absence, in human populations with different perchlorate exposures. For example, the prospective epidemiology study of Tellez et al. (2005) measured perchlorate in drinking water, breast milk and blood, and monitored iodine and thyroid hormone levels during pregnancy and post birth in mothers and their newborns. This study also monitored nitrate, selenium, iodine, lithium, and arsenic, which were known to be present in the environment of the three different populations studied by Tellez et al., and also which to some extent have been linked to thyroid dysfunction. This study also accounted for sources of perchlorate other than drinking water. Tellez et al. (2005) concluded that effects to the maternal or neonatal thyroid were not seen at water concentrations up to 114 ug/L. Specifically Tellez et al. (2005) state:

> We have conducted a longitudinal epidemiologic study among pregnant women from three cities in northern Chile: Taltal with 114 g/L, Chañaral with 6 g/L, and Antofagasta with 0.5 g/L perchlorate in the public drinking water. We tested the hypothesis that long-term exposure to perchlorate at these levels may cause a situation analogous to iodine deficiency, thus causing increases in thyrotropin (TSH) and thyroglobulin (Tg) levels and decreased levels of free thyroxine (FT4), in either the mother during the early stages of gestation or the neonate at birth, or in the fetus cause growth retardation. We found no increases in Tg or TSH and no decreases in FT4 among either the women during early pregnancy (16.1 4.1 weeks), late pregnancy (32.4 3.0 weeks), or the neonates at birth related to perchlorate in drinking water. Neonatal birth weight, length, and head circumference were not different among the three cities and were consistent with current U.S. norms. Therefore, perchlorate in drinking water at 114 g/L did not

ED_005043_00062728-00076

> cause changes in neonatal thyroid function or fetal growth retardation. Median urinary iodine among the entire cohort was 269 g/L, intermediate between that of pregnant women in the United States at National Health and Nutrition Examination Survey (NHANES) I and at NHANES III and consistent with current World Health Organization (WHO) recommendations. Median breast milk iodine was not decreased in the cities with detectable perchlorate. Analysis of maternal urinary perchlorate excretion indicates an additional dietary source of perchlorate.

EPA's modeling results were based in part on this prospective epidemiology study. But EPA should also use results from Tellez et al (2005) as a negative control, that is to validate its modeling outputs, recognizing that these outputs need to be consistent with Tellez et al.'s observations, and with other, similarly appropriate, prospective epidemiology studies. In fact, a precursor study to Tellez et al. (2005), that by Crump et al. (2002) was used as a basis of the RfD by Strawson et al. (2004a) and also commented on by NRC (2005, page 69):

> In addition to those calculations, the [NRC] committee compared serum concentrations of TSH and thyroid hormones reported by Crump et al. (2000) in children 6-8 years old with those children of similar ages in the United States during a comparable period (Zurakowski et al. 1999) as another approach to assessing whether data from the Chilean study might be useful for evaluating the U.S. experience. With the exception of serum T3, which is known to vary more depending on the assay method used, the mean serum thyroid hormone concentrations were not markedly different between U.S. and Chilean children. The mean TSH concentrations were somewhat higher in Chile but were not accompanied by decreases in serum T4 concentrations. Those results suggest that mean serum thyroid hormone concentrations in Chilean children were similar during the period to those in U.S. children of the same age. On the basis of the iodide-inhibition analyses, the additional comparisons, and a review of information on urinary iodide excretion, the committee concluded that the data from Chile could be considered in the evaluation of the U.S. experience with perchlorate in drinking water.

Collectively, these opinions show the value of the Chilean work and the usefulness of model calibration. The null hypothesis is that there is no relationship between perchlorate and measures of thyroid function. The alternative hypothesis is that there is. Since Tellez et al. (2005) saw no effect in hormone levels, these data do not allow the model to be evaluated for effects above their range of perchlorate exposures, where the null hypothesis might be rejected. However, Tellez et al. can be used to identify false positive predictions, that is, a positive model predication by EPA in the range of a negative observations by Tellez et al. would suggest a problem with EPA's model.

Therefore, we highly recommend that EPA carefully consider any deviations between their model output and observations from such prospective epidemiology studies, and specifically encourage EPA to carefully review the work of Tellez et al. (2005) for applicability to the US. This review would be consistent with NRC (2005) conclusion.

ED_005043_00062728-00077

Calibration of the EPA's model is expected to be challenging for three reasons:

- few quantitative criteria exist for markers in the range of hypothyroxinemia; thus, EPA will need to support it assumptions of 2.5th and 10th percentiles as defining this range;
- a large variability in iodine and perchlorate intake may be occurring in populations used in this calibration; and
- data are variable due to physiological and biochemical factors that are not addressed in the model; for example, the model does not address up regulation of symporter protein (more about this later).

One suggestion proposed by Lumen et al. (2013) would be to perform Monte Carlo analysis to address variability in model output. We encourage EPA to do this. Alternatively, or perhaps in addition, a positive control is also needed. EPA's model should be calibrated against observations where perchlorate has an effect on T4 (total or free) or TSH. In this regards, a wealth of experimental animal information exists that may be helpful in this modeling. The TERA Center at the University of Cincinnati, College of Medicine has all of this information on file, and it is freely available for anyone to view.

The following comments are focus on the charge questions for the perchlorate peer review panel and incorporate recommended changes to the charge questions in **red text** submitted by the American Water Works Association on October 21, 2016.

Charge question 1:

Please comment on the following aspects of the BBDR model structure and integration of the submodels for iodide/thyroid hormones and perchlorate for each of the life stages of focus (i.e., lactating mother, breast-fed infant, and bottle-fed infant):

A. **Does the developed model structure adequately and accurately describe the physiology and kinetics of iodine, thyroid hormones, and perchlorate during different life stages specified above? Please specifically note the strengths and weaknesses of the model structure for each life stage.**
B. **Are the physiological and kinetic parameters for iodine, thyroid hormones, and perchlorate for these life stages supported by the published sources for those parameters or data used to identify parameters via calibration? Please identify any critical data gaps or additional data on these model parameters.**
C. **Does the body up regulate the production of thyroid sodium-iodine symporters in the area of hypothyroxinemia prior to the stimulation of TSH? If so, how might this up regulation affect the modeling results?**

Response

One question that is not currently addressed by the model is the effect of increased sodium iodine symporter (NIS) expression on thyroid iodine transport in the presence of perchlorate-induced expression of the NIS gene, and more dramatically, the

ED_005043_00062728-00078

increase in production of the associated protein(s). For example, it is well documented that iodine deficiency, and possibly perchlorate exposure, facilitate baso-lateral localization of the iodine symporter, making it easier for the thyroid cell to acquire iodine. Further, simple Michaelis Menten kinetic modeling of transporter velocity, with the inclusion of terms for competitive perchlorate inhibition, suggests that modest increases in transporter expression (i.e. 2 to 5-fold expression) could provide compensation for perchlorate inhibition over a range of serum iodine concentrations. This may be an important factor since a perchlorate concentration of 150 ppm (~15 mg/kg-day) was reported to induce NIS mRNA in postnatal day 25 rat pups by about 1000%, and in dams by 5-fold (Taylor, 2008. At this high dose, NIS protein levels could be induced to even higher levels than indicated here since posttranslational stabilization of both the transcript and the receptor protein have been implicated as important regulators of symporter expression.

While an open question remains in the dose-response relationship between perchlorate concentration and NIS induction, and whether a threshold dose exists below which little or no change in NIS expression occurs, EPA's model should be able to adequately account for homeostatic responses at steady-state perchlorate levels. Such responses may include compensatory changes that reestablish normal T4/fT4 levels; compensatory changes are not typically considered adverse. Model predictions should not focus on acute or temporally immediate effects of perchlorate; rather steady-state changes at equilibrium reflective of environmental exposures. A prediction on immediate perchlorate effects could be misleading if homeostasis is rapidly reestablished by normal compensatory physiological changes.

Therefore, we highly recommend that EPA consider how its modeled perchlorate dose response assessment might be modified by up regulation of symporter expression in the perchlorate dose range of interest. At the very least, such up regulation, if occurring and not otherwise addressed, would lead to a more conservative RfD or MCLG, all other factors remaining the same.

Charge question 5:

Given the lack of a specific quantitative clinical definition of hypothyroxinemia for the specific life stages evaluated (pregnant mothers, infants and lactating mothers) and that reference intervals of thyroid hormones reported in the literature are influenced by many factors (life stage differences, analytical method used, laboratory utilized, ethnicity, iodide nutrition, population size etc.), EPA developed a normalization procedure to derive hypothyroxinemia reference ranges.

A. **Please comment on whether the development of this hypothyroxinemia reference ranges ~~-~~is consistent with EPA's definition of critical effect, that is the first adverse effect or its known precursor as dose rate increases. Might a different effect such as changes to TSH be a more appropriate critical effect? If the former is ~~on the~~ more appropriate, then is this particular hypothyroxinemia range derived for pregnant mothers, fetuses,**

ED_005043_00062728-00079

lactating mothers, breast-fed infants and bottle-fed infants appropriate.

Response:

If hypothyroxinemia is considered to be the critical effect, then the development of a normalized range for hypothyroxinemia among studies seems appropriate, and EPA is to be commended for developing an easy to understand tool to effect its modeling.

However, the choice of hypothyroxinemia is not consistent with EPA's definition of critical effect, that is, the first adverse effect or its known precursor [singular] that occurs at dose rate increases (EPA, 2016c). Nor has EPA chosen such changes as sole critical effects with other of its assessments where the thyroid gland is impacted, as shown on Table X. Furthermore, the EPA model is a review of 3rd trimester hormone changes, however, neurological changes are expected from 1st trimester, which evokes questions including, why is a decrease in fT4 considered adverse for 7 days postnatal if this time is not associated with 1st trimester exposures? What level of decrease is considered adverse? Is maternal hypothyroxinemia itself the critical effect, or is it a "springboard" to possible neuro-developmental effects?

The concept of critical effect is embedded in a continuum of effects potentially associated with any exposure to xenobiotics and reflects a sequence of effects of differing severity. From least to most severe this continuum includes, adaptive effects, compensatory effects, the critical effect, adverse effects, and frank effects.

As EPA colleagues know, this continuum starts at:

- Low dose with upstream indicators of change, or adaptive effects, where the organism's ability to withstand a challenge is enhanced. Doses associated with such effects are often referred to as No Observed Adverse Effect Levels (NOAELs). The concept of hormesis may also be relevant here.
- As dose increases, compensatory effects occur, which enable the organism to maintain overall function without further enhancement or significant cost. Doses associated with such effects are also often NOAELs. Some of these effects might be judged to be the critical effect.
- As dose further increases, the critical effect is reached. This is the first adverse effect, or its known precursor, that occurs to the most [relevant or] sensitive species as the dose rate of an agent increases. Note that the bracketed phrase "relevant or" is important since the most relevant specie is always preferred over the most sensitive specie (e.g., if data shows that the rat is more sensitive than the human, the human data are still preferred), but when such information is not available, data from the most sensitive specie are chosen. Also the term "precursor" in this definition is singular, meaning the immediate precursor, not just any prior effect. This restriction is important both because it ties the concept of critical effect into common medical practice and because the resulting dose response—such as an RfD—is more meaningful. Specifically, without the

ED_005043_00062728-00080

restriction any RfD can be estimated.[1] Doses associated with such effects are Lowest Observed Adverse Effect Levels (LOAELs). The highest NOAEL below this LOAEL is generally used in the dose response, and the focus is on determining this NOAEL in a sensitive population.

- As dose further increases, the critical effect is exceeded, and adverse effects are manifested as biochemical changes, functional impairments, or pathologic lesions. These progressively more severe effects impair the performance of the organism, and/or reduce its ability to respond to additional challenges. At some point these adverse effects become manifestly overt and irreversible, and frank effects or disease ensues.

For EPA's perchlorate modeling, this continuum of effects means that determination of the critical effect is of utmost importance in developing RfDs and other dose response assessment values. This is because all chemicals will elicit effects at some dose, and the effects of many of these chemicals are beneficial (e.g., any macro or micro nutrient at essential levels and drugs when administered at recommended doses). However, all chemicals also elicit adverse responses. It follows that expert judgment, involving many disciplines, is needed to determine the critical effect, that is, the first adverse effect or its known precursor.

NRC (2005, page 111) defined the first adverse effect for perchlorate exposure as hypothyroidism (see attached Figure Z). This determination should guide EPA in its choice of the critical effect. According to both the NRC determination and EPA's definition, the critical effect would be hypothyroidism or its immediate precursor, thyroid hypertrophy/hyperplasia.

Given data on both hypothyroidism and hyperplasia/hypertrophy, the risk assessment focus would likely fall to the precursor lesion, that is, either hyperplasia and/or hypertrophy. Unfortunately, it is often difficult to determine modest stages of thyroid hypertrophy or hyperplasia in humans since routine biopsies to monitor such modest endpoints are contraindicated. The next most logical endpoint to monitor would be changes in thyroid and pituitary hormones, with changes in TSH more closely associated with doses that cause hyperplasia and/or hypertrophy. Thus, changes in TSH, or concurrently, changes in T4 that are expected or assumed to lead to changes in TSH, may be an appropriate focus for EPA's selection of critical effect. This means specifically, a change in fT4 to a level of the lower 2.5th percentile of the population as described on EPA (2016d, page 17):

> …and that hypothyroxinemia occurs for fT4 levels between the 2.5th and 10th percentile for the entire population. When fT4 falls below the 2.5th percentile for the entire population in a life stage, it is assumed that TSH levels would be

[1] Many examples of appropriate use by different groups are found on International Toxicity Estimates for Risk (*ITER*) database available at http://toxnet.nlm.nih.gov. An example of where this was not done appropriately is the NAS perchlorate assessment (2005, page 111). For a commentary on this inappropriate choice, see also Strawson et al., (2005).

ED_005043_00062728-00081

sufficiently elevated to trigger hormonal feedback, invalidating the model predictions.

Therefore, to determine an RfD or MCLG, EPA could select as its point of departure the perchlorate dose associated with a lower 2.5th percentile of fT4 in the chosen sensitive population. If so, then EPA will also need to support its assumption that this lower 2.5th percentile evokes changes in TSH, which, although not technically the critical effect, is a good surrogate for thyroid hyperplasia and hypertrophy, which is/are the known precursor to the first adverse effect from perchlorate exposure (NAS, 2005, page 111). Alternatively, EPA could revise its model so that changes in TSH could be explored as the basis for its point of departure (POD). Again, changes in TSH are closer to the critical effect than are changes in fT4.

However, in either case, EPA should recognize that basing a drinking water standard on a non-critical effect (the first adverse effect or an immediate precursor) is unprecedented and has broad implications for the overall regulatory approach. Thus, EPA will need to carefully explain that while hypothyroidism is the expected first adverse effect from perchlorate exposure (as per NAS, 2005, page 111), and while hyperplasia/hypertrophy are the immediate precursor, that neither one of these effects is easily monitored in human populations and, thus, pituitary or thyroid hormone changes, recognized as non-adverse and non-critical effects, are being used as points of departure for perchlorate. Importantly, such a choice by EPA for perchlorate does NOT indicate an overall change in policy. But rather, is necessitated by the unique perchlorate database. Especially since all chemicals have some effect on the human body at low levels, many of which are not adverse, EPA's decision needs to be carefully explained. Otherwise this decision has the potential to divert limited resources to actions that seek to mitigate nonadverse, or otherwise *de minimis* public health risks.

B. Based on the perchlorate dose level at which each life stage is predicted to become hypothyroxinemic (for a given iodine ingestion rate), it appears that the lactating mother is much more sensitive than the breast-fed infant for PND 30-90. In part this occurs because breast feeding reduces the iodide available for the maternal thyroid. Is this prediction biologically realistic and clinically relevant, and if so, should the subsequent analysis also consider the lactating mother as a life-stage of concern for MCLG derivation?

Response: From a clinical perspective, lactation is associated with iodine uptake in the breast, which is why medical doctors avoid treating lactating mothers with radioactive iodine. Furthermore, there is a well-documented clinical increase in thyroid hormone requirements during pregnancy, which is addressed by increasing thyroid hormone supplementation for hypothyroid patients, but typically with return to pre-pregnancy dosage postpartum. However, colleagues of the University of Cincinnati, College of Medicine are unaware of any clinically increased rate of hypothyroidism in breast-feeding women compared to those choosing to feed their children formula. Thus, pregnancy and its increased thyroid hormone requirements have a far greater impact on the mother than breast-feeding.

ED_005043_00062728-00082

We encourage EPA to further explore whether this lack of hypothyroidism in the maternal population who choses to breast-feed their infants is correct. If correct, then EPA's model that projects hypothyroidism in breast-feeding women is not correct.

Table X. Chemicals on EPA's Integrated Risk Information System (IRIS) with Thyroid Changes as one of the Critical Effects

Chemical Name	CASRN	Route	Assess. Type	Critical Effect or Tumor Type (selected)
Acrylamide	79-06-1	Oral	Cancer	Thyroid tumors and tunica vaginalis mesotheliomas
Apollo	74115-24-5	Oral	Noncancer	Four groups of 6 male and 6 female dogs were given diets containing varying doses of Apollo for 1 year. At dietary levels of 1000 and 20,000 ppm, the effects on organ weights included hepatocyte enlargement with eosinophilic cytoplasm; increased liver, thyroid, and adrenal weights; and elevated serum cholesterol, triglycerides, and alkaline phosphatase. Further studies in a 2-year feeding oncogenic rat study revealed that Apollo increased bile flow rate and shifted the pattern of thyroxine excretion to the feces, suggesting that Apollo may enhance clearance of thyroid hormones. The proposed mechanisms postulated that Apollo increased bile flow, causing an increase in metabolism and excretion of thyroxine. The reduced circulating thyroxine stimulated the pituitary gland through the hypothalamus to produce increased TSH. The elevated TSH stimulated the follicular cells and resulted in increased thyroxine and decreased colloid, follicular cell hyperplasia, hypertrophy and neoplasia in the male rat at the termination of the chronic study.
Benzyl chloride	100-44-7	Oral	Cancer	Thyroid, C-cell adenoma/ carcinoma
Bromate	15541-45-4	Oral	Cancer	Testicular mesothelioma, renal tubular adenoma and carcinoma, and thyroid follicular cell adenoma and carcinoma
Chlorine cyanide	506-77-4	Oral	Noncancer	Decreased weight gain, significant decreases in thyroxin levels and thyroxine secretion rates, and myelin degeneration in rats at 30 mg/kg/day cyanide (70 mg/kg/day chlorine cyanide); NOAEL: 10.8 mg/kg/day cyanide converted to 25.3 mg/kg/day of chlorine cyanide Proliferation of glomerular cells of the kidney and follicular cells that were low in height and

ED_005043_00062728-00086

Chemical Name	CASRN	Route	Assess. Type	Critical Effect or Tumor Type (selected)
				accumulation of colloid in the thyroid glands in young sows at about 9.45 mg/kg/day CN
Cumene	98-82-8	Inhale	Noncancer	Increased kidney weights in female rats and adrenal weights in male and female rats
Cyanogen bromide	506-68-3	Oral	Noncancer	Decreased weight gain, significant decreases in thyroxin levels and thyroxine secretion rates, and myelin degeneration in rats at 30 mg/kg/day cyanide (122 mg/kg/day cyanogen); NOAEL: 10.8 mg/kg/day cyanide converted to 44 mg/kg/day of cyanogen
Dacthal	1861-32-1	Oral	Noncancer	Effects on the lungs, liver, kidney, thyroid and thyroid hormones in males and females and eyes of females occurred (increased organ weight as well as an increase in the incidence and severity of follicular cell hypertrophy, hyperplasia and basophilic clumped colloid). Additionally, a dose-related decrease in thyroxine (T4) occurred throughout the study, and triiodothyronine (T3) was decreased in a dose-related manner at 52 weeks. Thyroid stimulating hormone (TSH) values were elevated at 52 weeks (dose related) and at 104 weeks (no dose response).
1,2-Dibromo-ethane	106-93-4	Oral	Cancer	Forestomach tumors, hemangiosarcomas, thyroid follicular cell adenomas or carcinomas
Dodine (ARCHIVED)	10/3/2439	Oral	Noncancer	Thyroid toxicity including changes in the shape of follicular epithelial cells of the thyroid from squamous to cuboidal and low columnar in 4/4 dogs; increased vascularity; and partially filled follicles that stained less intensely
Ethylene thiourea	96-45-7	Oral	Noncancer	Increased incidence of thyroid hyperplasia
Hydrogen Cyanide and Cyanide Salts	Various	Inhale	Noncancer	In workers (n=36) exposed to HCN for 5 – 15 years in three electroplating factories, statistically significant altered rates of iodide uptake by the thyroid, thyroid enlargement, and CNS symptoms were reported. Twenty of the exposed workers (26%) were identified with mild to moderate thyroid

				enlargement. Radioactive iodine uptake measured following a 2-day break in HCN exposure indicated statistically significantly elevated iodide uptake after 4 hours (38.7 compared to 22.4%) and 24 hours (49.3 compared to 39.9%) as compared to controls In a study of silver-reclamation workers (n=36) examined an average of 11 months following exposure, serum thyroid stimulating hormone (TSH) levels in workers were significantly elevated relative to laboratory controls. T3 uptake in the highest exposed workers (n=9) was statistically significantly elevated compared to laboratory controls In an occupational study of electroplating workers exposed to HCN, workers (n=35) exposed for 5 years had significantly decreased T3 (48%) and T4 (37%) and significantly increased TSH (142%) as compared to controls. A significant negative correlation between T4 and SCN- concentrations were observed among 6 or 10 pigs per group (sex not specified and number of animals unclear due to inconsistencies in reporting) that were treated with KCN administered in the diet for 10 weeks, an in increase of 24% in thyroid weight was seen at 4.3 mg/kg-day. Histologic alterations were reported in the thyroid, liver, kidney, and CNS in all dosed animals. However, no incidence data or statistical analyses were provided for these histologic findings, precluding a characterization of the dose response for these effects. In a 24-week evaluation of the effects of gavage administration of KCN on behavior and thyroid function in miniature pigs, both triiodothyronine (T3) and thyroxine (T4) demonstrated a dose-related decrease (23 and 13%, respectively) that was statistically significant by week 18 of the study. In a 14-week evaluation of the toxicity of diet supplemented with NaCN corresponding to 0 or 1.04 mg/kg-day CN- in 22-week-old mongrel dogs (six males per group), an evaluation of the thyroid of

ED_005043_00062728-00094

SUMMARY OF INTERTOX COMMENTS

On September 30, 2016, US EPA published a notice announcing the release of materials for public comment in the Federal Register (81 FR 67350). The materials will undergo peer review in support of US EPA's Safe Drinking Water Act determination to regulate perchlorate. The Agency requests comments on both the draft Biologically Based Dose-Response (BBDR) Model and an accompanying draft model report titled "Biologically Based Dose-Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses" (the "Report"). Prior to this submission, Intertox commented on the charge questions and the list of peer review candidates to US EPA's managing contractor, Versar, Inc. (Provided as Appendices A and B in our full report).

In this document we focus our scientific comments on the BBDR model and the US EPA Draft Report. This will be the first time US EPA has used a BBDR Model to inform development of a Maximum Contaminant Level Goal (MCLG).

Support for US EPA's Process

The use of the best available science—key to any scientific endeavor—is imperative as the basis to impose regulatory limits for any chemical.

- We agree that a science-based BBDR or physiologically-based pharmacokinetic/ pharmacodynamic model (PBPK/PD) model for the assessment of relevant physiological parameters can inform US EPA on the possible health impact of perchlorate exposure. This process, when done transparently and systematically, is scientifically defensible and Intertox supports such a process.
- The Agency has bifurcated, we believe appropriately, the scientific work into two parts with separate peer reviews. The first and current peer review is focused on the BBDR model and the second will focus on how to use the model to define an adverse effect level. These require different expertise to evaluate the issues and these peer reviews will produce stronger scientific assessments when they can be more focused.
- The Agency has sought the assistance of a peer review of the BBDR model and associated documents. US EPA has also provided opportunity for public and stakeholder comments; we intend these to be helpful to US EPA and the peer reviewers. We hope there will be the opportunity for public comments at the peer review meeting.

Improvements to US EPA Draft Model Report

US EPA's Report can be improved using a more systematic approach, increasing transparency, and providing additional information. Since not all of the peer reviewers will have modeling experience, they will rely on US EPA's report as the only information on the model and will not conduct an independent assessment. The summary of our review of the Report is:

- The document can be improved with a more systematic approach and greater transparency. For example, the literature review, as US EPA explains it, was discontinued in 2013, yet the Report uses several references published after 2013 leaving it unclear why these were included while others were excluded. Additionally, when references for parameters are cited, the reference may be for another model, not the original study, leaving the reader unclear as to what literature is available for the parameter and why this value was chosen over others in the distribution for use in the model.

ED_005043_00062728-00095

- The Agency's cited literature will benefit by a complete literature review to support its conclusions. The portion of the data that the document relies upon is limited and would raise issues for US EPA on fundamental scientific rigor.
- The figures presented in the Report make it difficult to interpret the relevant data, that is, daily doses below 1 μg/kg-d. US EPA should consider tables of data (rather than figures) and focus the figures on the relevant environmental dose range for perchlorate (0-1 μg/kg-d).

Improvements to US EPA's BBDR Models

The model can be improved providing additional support in integrating the model code, increasing transparency in the output, and improving the ability of the model to predict both perchlorate and iodine deficiency with no perchlorate. For US EPA's two models, the model code was released in both acslX (Aegis Technologies, Inc.) and "R" languages (BBDR Models). The summary of our review of the model is:

- The model's only output being considered is the effect on free thyroxine (fT4) and no other measures of thyroid function. To understand the complex feedback and homeostatic mechanisms in the hypothalamic-pituitary-thyroid axis, several measures of thyroid function should be modeled (e.g., TSH, thyroglobulin, and thyrotropin releasing hormone).
- The Agency must increase transparency and resolve the inconsistencies in the BBDR model code. For example, it is nearly impossible for a peer reviewer to implement a working model by reading the documentation provided by US EPA. The fact that codes for two different platforms were available allowed us to query one code set to understand a second the code.
- The models are extremely difficult to set up and run and we have great concern that the compressed time frame for peer review will limit the ability of the peer reviewers to critically review the model. This includes the instructions, definition of parameters, and download of all software necessary to use the model.

Overarching Concerns

The Agency would improve the process and increase scientific rigor greatly by addressing the following:

- The endpoint of hypothyroxinemia, despite the US EPA's recent SAB review, is not a scientifically robust endpoint for evaluation of an adverse effect. Other thyroidal parameters (e.g., TSH and fT4) will be more consistent with adverse thyroidal effects and clinical values in the literature.
- The Model does not include other goitrogens with the same mechanism of action as perchlorate. These should be included in the BBDR model analysis. There are accepted methods to account for potency and mass that would increase the applicability to the Model.
- A fundamental concept in modeling the key mechanism of action of perchlorate (and other goitrogens) is to predict iodine deficiency without the influence of any other agents. Modeling iodine deficiency accurately would be the necessary first step in ensuring the credibility of the BBDR models.
- The Model predicts changes in thyroid hormone well below the known threshold for effects. As noted in the figure below, we have concerns about the model because it is inconsistent with the decades of scientific literature in animals and humans as well as the uncontested

ED_005043_00062728-00096

mechanism of action. For example, the model predicts changes in fT4 in the lactating woman with any addition of perchlorate. NRC (2005) estimated that approximately 75% inhibition of iodide uptake daily (a non-adverse precursor to thyroid hormone changes) would be necessary to cause any adverse effect. US EPA's model predicts that 75% iodide uptake would require a dose of over 500 µg/kg-d in a lactating woman (Figure B-7 in the Report). A dose of 500 µg/kg-d has not been reported to cause changes in thyroid hormone (Greer *et al.*, 2002; Braverman *et al.*, 2006). The model should be able to reliably predict such data.

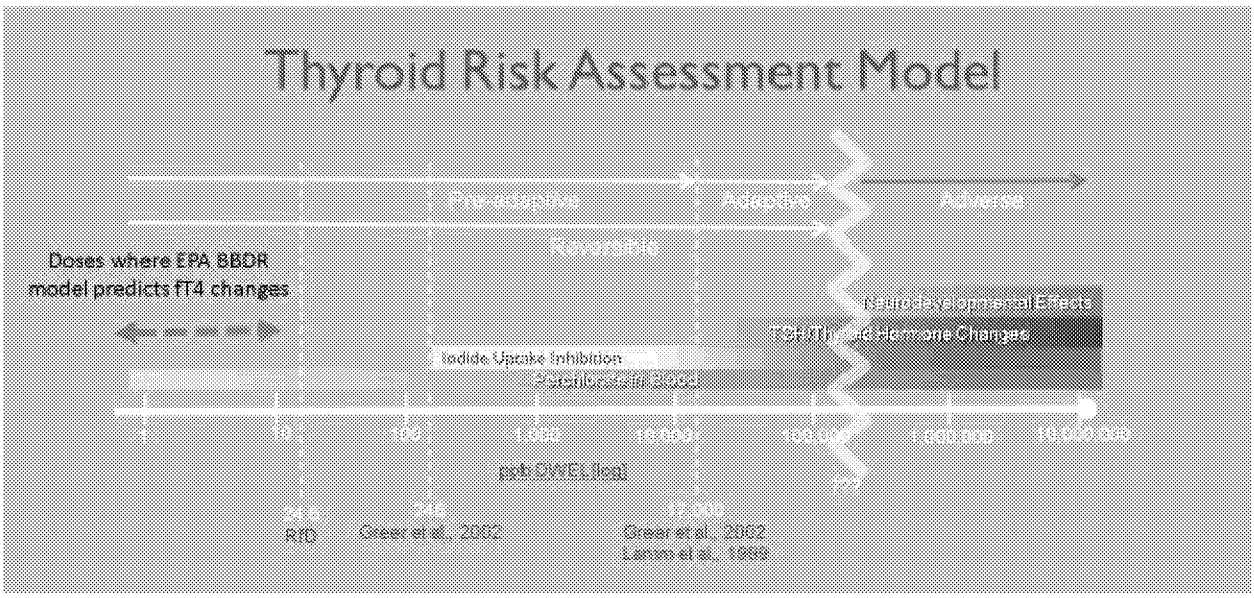

FIGURE A. REPRESENTATION OF THE DOSE-RESPONSE CURVE (IN WATER CONCENTRATION USING STANDARD US EPA CONVERSION FACTORS) FOR PERCHLORATE

See Figure 2 for more detail.

- It is difficult to fully review the model without knowing how US EPA will use it. It is scientifically useful to know how the data output from a BBDR model will be used as it allows for the understanding of the level of sensitivity required by the model.
- Extend the time for evaluation of the model. As noted in comments to Versar (Appendices A and B), we do not understand how US EPA expects a qualified scientist to download, troubleshoot, evaluate model code, evaluate model parameters, review US EPA's Report, and provide meaningful comments for this peer review given the short time for evaluation. We appreciate the additional 10 days, however, that still does not allow the thoughtful and scientific approach one needs to evaluate any BBDR model.

Overall, we agree with the approach and process US EPA is taking. We commend US EPA on using an improved method compared to the algebraic method for deriving a regulatory value. We are deeply concerned that the work done thus far in developing this model will be abandoned because US EPA has not been able to transparently deliver, describe, and predict hypothesized effects of a chemical exposure because it has not fully developed and tested a complex model. With the best available science in mind, we hope these comments will be useful to US EPA and to the peer reviewers in focusing their review.

ED_005043_00062728-00097

1.0 INTRODUCTION

On September 30, 2016, US EPA published a notice announcing the release of materials for public comment in the Federal Register (81 FR 67350). US EPA released its document titled "Biologically Based Dose Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses" (the "Report") and the code (the "Model") for its Biologically Based Dose Response (BBDR) model in both acslX (Aegis Technologies, Inc.) and "R" languages. There were actually two models that were released: the pregnancy model (pregnant woman and fetus) and lactation model (lactating woman and infant). Prior to this submission, Intertox commented on the charge questions and the list of peer review candidates to US EPA's managing contractor, Versar, Inc. (Provided as Appendices A and B).

In this document, we focus our scientific comments on the BBDR models and the US EPA Report. US EPA has not yet released any information on how it will derive a Maximum Contaminant Level Goal (MCLG) using information from the models. In June 2016, US EPA stated:

> EPA is considering deriving a perchlorate MCLG by linking BBDR model output to alterations in thyroid hormone status that result in alterations in neurodevelopment. The draft approach for deriving a perchlorate MCLG outlines an assessment of the literature linking alterations in thyroid hormone status to alterations in neurodevelopment. Based on the results of this literature review, the report describes potential approaches to set the MCLG based on the availability of the current literature and the output of the BBDR model, predicting the effects of perchlorate on serum thyroid hormone concentrations in infants exposed via ingestion of formula mixed with contaminated drinking water or breast milk (see 81 FR 10617, March 1, 2016).

In the interest in providing as useful summary of information on the Report and Model, we will summarize what US EPA is doing to ensure use and application of the best available science (Section 2.0), suggest improvements for the Report (Section 3.0), suggest improvements for the Model (Section 4.0), and discuss overarching concerns with both the model and report (Section 5.0). We hope that this information will be useful for both US EPA and the Peer Review in the interest of promoting strong scientific support for the regulatory process.

2.0 SUPPORT FOR US EPA'S SCIENTIFIC PROCESS

US EPA made the decision to regulate perchlorate in drinking water under the Safe Drinking Water Act. The use of the best available science—key to any scientific endeavor—is imperative as the basis to impose regulatory limits for any chemical. Every scientist understands that we live in a world of chemicals, some harmful, some helpful, and some necessary to life; the key to regulation is using scientific knowledge to determine what are safe levels of exposure. Often, there is little information to support regulatory determination. Perchlorate is unique in that there are more than 60 years of scientific studies for this chemical.

We agree that a science-based BBDR or physiologically-based pharmacokinetic/pharmacodynamic (PBPK/PD) model for the assessment of relevant physiological parameters can inform US EPA on the possible health impact of perchlorate exposure. This process, when done transparently and systematically, is scientifically defensible and Intertox supports such a process.

We further agree with the Agency's decision to bifurcate the scientific assessment of its scientific work into two parts. The first, and current part regards the BBDR model review. The second part will

ED_005043_00062728-00098

be an evaluation of the methods for applying the BBDR models to possible adverse effects. These require different expertise to evaluate the issues at hand and these peer reviews will be stronger when they can be more focused.

Finally, we agree with US EPA's decision to seek peer review on its current BBDR model and associated documents. We are pleased that there is an opportunity for public and stakeholder comments. Finally, we trust that the peer review will be conducted in a manner that allows collaboration between peer reviewers, the public, and stakeholders at the upcoming peer review meetings.

3.0 IMPROVEMENTS TO THE US EPA DRAFT MODEL REPORT

The report can be improved using a more systematic approach, increasing transparency, and providing additional information. Since not all of the peer reviewers will have modeling experience, they will rely on US EPA's report as the only information on the model and will not conduct an independent assessment. Without improved clarity on the sources and documentation of the parameters, a better understanding of what effects key components have on the modeling results, and better presentation of data, it may be possible to dismiss the analysis, particularly when the conclusions are not well supported.

The Model Report includes a main document that describes the model development and parameterization, calibration, a preliminary dose response assessment, and a sensitivity analysis. The appendices include parameter definitions, changes that the Agency made to the model, an analysis of differences among the various life stages, perchlorate clearance analysis, and an assessment of population fT4 levels (definition of hypothyroxinemia). The BBDR Model code and supporting document was initially released with a 45-day comment period that was subsequently extended by 10 days.

3.1 Aligning the Report to standard scientific report fundamentals

US EPA describes the literature review that was conducted as part of this process. Based on the description on p. 22 of the Report, US EPA only searched PubMed and this search was conducted in December of 2013. As the release date of the Report was September 2016, it is unclear why US EPA failed to update its search. Three years may have produced relevant data to strengthen the model inputs and, at a minimum, it is simply the scientifically thorough process, particularly given the importance of the development of this model for the regulatory process. In addition, no summary of the literature review is included. The number of studies found is given, but what those studies report and justification for using or not using them is not included in the Report.

It is also clear that US EPA did use certain data from papers published after 2013. A review of the References shows seven papers (excluding one by the lead author of the Report which is listed as "in press") published in 2014-2016. Since these were not found as part of the systematic review of the literature, it is unclear why these were chosen and added to the exclusion of others.

In many cases where the literature for a parameter is cited (e.g., Table 4 of the Report), the citation is for another model (e.g., Fisher *et al.* (2016), Lumen *et al.* (2013)). This suggests that the value is given based on a cited report, but the cited studies are not primary literature sources of the actual data. If one is to evaluate US EPA's parameter, it would require independent evaluation of the cited model report (e.g., Lumen *et al.* (2013)) which would cite the paper documenting the study that the value is derived from. It is unlikely that a peer reviewer will conduct this type of evaluation given the limited time for review.

ED_005043_00062728-00099

Finally, the Report is not specific about wording it uses in its evaluation. For example, US EPA uses the word "adequate" or "within the range" as descriptors of its analysis. For example, "Overall, the model predictions were considered adequate" (p. 60 of the Report). These descriptors lack any specificity. US EPA should explain what threshold (e.g., within one standard deviation) is necessary for results or predictions to be "adequate" or "in the range" and what would constitute results that are inadequate. Left as undefined, it is misleading to the reader who may consider "adequate" to have to some intrinsic relative standard.

3.2 Transparency in the analyses of report content

When describing and documenting a BBDR model, there are certain standard evaluations that should be included, well-documented so they can be replicated, and summarized in a meaningful way. US EPA has not accomplished this in the Report. The Report has headings that describe calibration, local sensitivity analysis, and evaluation of model structure changes. However, the documentation of these activities, among others, is incomplete; it's unclear whether these were done to scientific community standards and what effect these had on the overall analysis. For example, US EPA presents the results of the sensitivity analysis. First, these were conducted for the formula-fed and breast-fed infants only. It is unclear why US EPA focused on these groups only. Second, US EPA chose a 1% change from default values, again without giving any justification for the decision. Third, US EPA displays both graphics and tables with the results of the sensitivity analysis, but does not describe or summarize the results other than to say

> …the influential parameters were time-dependent, iodine-dependent, and perchlorate-dependent. The influence of perchlorate on iodine was more significant in the breast-fed exposure because the low predicted iodide transferred in milk at the lower maternal exposure of 75 μg/d.

A reader unfamiliar with conducting a sensitivity analysis on a PBPK model would have no context for why this was being done, what the results are supposed to mean for the model and its results, and how to use this information to interpret US EPA's model output.

Similarly, US EPA presents an appendix on model structure changes; however, does not summarize what these changes were and what effect they have on the relevant output of the model: fT4 changes in pregnant women, fetuses, lactating women, and infants. In our review of three parameters (Km for binding of perchlorate to the NIS, Vmax for transfer of perchlorate in breast milk, and the permeability-area diffusion constant for iodine transfer to breast milk), US EPA's changes all make the model predict lower fT4 levels (Table 1). When multiple parameters are altered to increase the conservatism individually, the cumulative effect may be an overly conservative and unrealistic model. US EPA does not describe the cumulative effect of all of the changes to the overall model.

3.3 Presentation of results

One of our main concerns with the Report is the presentation of data. The only way the relevant output of the model (fT4) is presented is in figures. These figures are dose-response curves with fT4 plotted against perchlorate dose. Each curve represents a different iodine intake level (75 μg/d up to 250 μg/d). Presenting the data in this way creates several concerns: uncertainty is unclear, relevant doses are disregarded, and it's difficult to compare small variations in doses.

ED_005043_00062728-00100

TABLE 1. CHANGES IN FT4 BASED ON US EPA'S CHANGES TO SELECTED MODEL PARAMETERS

Parameter Assumption	Population	Assumption (A) value ["New" US EPA Value]	Assumption (B) value [Previous Value]	acslX A	acslX B	% Change
Km for Binding of Perchlorate to the NIS (KMNIS_P)	Pregnant Woman	6×10^4 ng/L (= 6.0e2 nmol/L)	1.6×10^5 ng/L (= 1.6e3 nmol/L)	10.1786	10.3600	-1.75%
Km for Binding of Perchlorate to the NIS (KM_TPNG)	Lactating Woman	6×10^4 ng/L (= 6.0e2 nmol/L)	1.6×10^5 ng/L (= 1.6e3 nmol/L)	11.1056 (7 day)	11.1057 (7 day)	-0.0009% (7 day)
				7.4284 (60 day)	7.4297 (60 day)	-0.0175% (60 day)
Vmax for Perchlorate Transfer to Breast Milk (VMAXC_MKP)	Lactating Woman	4.52e4 ng/h/kg$^{0.75}$	2.0e4 ng/h/kg$^{0.75}$	11.1056 (7 day)	11.1063 (7 day)	-0.0063% (7 day)
				7.4284 (60 day)	7.4282 (60 day)	0.0027% (60 day)
Permeability-area Diffusion Constant for Iodine Transfer to Breast Milk (PAMKC_I)	Lactating Woman	0.001 L/h/kg$^{0.75}$	0.002 L/h/kg$^{0.75}$	11.1056 (7 day)	11.1087 (7 day)	-0.0279% (7 day)
				7.4284 (60 day)	7.4713 (60 day)	-0.5742% (60 day)

US EPA has stated that there is uncertainty in the modeling results for 75 and 100 µg/d maternal intake of iodine. US EPA states

> Model predictions are also shown for 100 and 75 µg/d iodine, but the results for 100 µg/d are near the bottom of the provisional reference range, and are much more uncertain. At 75 µg/d the pregnant mother is predicted to be below the provisional 2.5th population percentile, hence in the hypothyroid range, even without perchlorate exposure (Figure 10, lowest curve, shown in grey). Those results are included, even though the entire 75 µg/d curve is currently considered uncertain, in the event that it is later determined that model predictions are valid for lower levels of fT4.

Although US EPA suggests that at some later time, the data may prove to have greater predictive power (it is unclear how this would occur), it is misleading to include it here currently. It appears to the reader that there are doses of perchlorate that drive fT4 far below US EPA's hypothyroxinemic range. EPA should not include data which are considered uncertain, such as the 75 µg/d iodine intake.

The Report figures present doses of perchlorate from 0 to 20 µg/kg-d (equivalent of 700 ppb in drinking water assuming a 70-kg adult drinking 2 L/d). US EPA states

> Comparing the predictions with the perchlorate sub-model to the radio-iodide uptake data of Greer *et al.* (2002) (for adults, the lactating mother, see Appendix B) indicated that the model is only accurate for prediction of iodide uptake inhibition up to an exposure level of ~ 100 µg/kg/d perchlorate. However, dose-response analyses were restricted to 0-20 µg/kg/d perchlorate, since that is the range of interest and likely application, and because predicted ft4 levels for many of the life-stages and iodine intake levels fell below their respective reference levels in this range.

Even doses up to 20 µg/kg-d are much greater than relevant for environmental exposures. The average dose of perchlorate from all sources in the US based on NHANES is 0.066 µg/kg-d and the

95th percentile is 0.234 µg/kg-d (Blount *et al.*, 2010). The RfD for perchlorate is 0.7 µg/kg-d (US EPA, 2005). If US EPA is intending to use this model to determine an MCLG for perchlorate, it is important to reliably evaluate doses in the relevant range both for exposure and for potential regulatory values. It is clear that doses greater than 1 µg/kg-d are irrelevant to this exercise (Figure 1).

This is a difficult point to understand given the figures as the only means to interpret the data. The line are bulky and difficult to discriminate between. In other figures where actual data from calibration studies are presented, the markers are incorrectly sized for readability or are a shape/design that has low quality. A table presenting the model data should also be included. The code to do so is not included in the model which requires an understanding of computer coding and model output to write code to accommodate this. For example, Intertox was able to do this to evaluate the data more precisely. In the pregnant woman (Figure 1), the corresponding table of data (Table 2) would clearly demonstrate no hypothyroxinemia with iodine intake of 150 µg/d and greater.

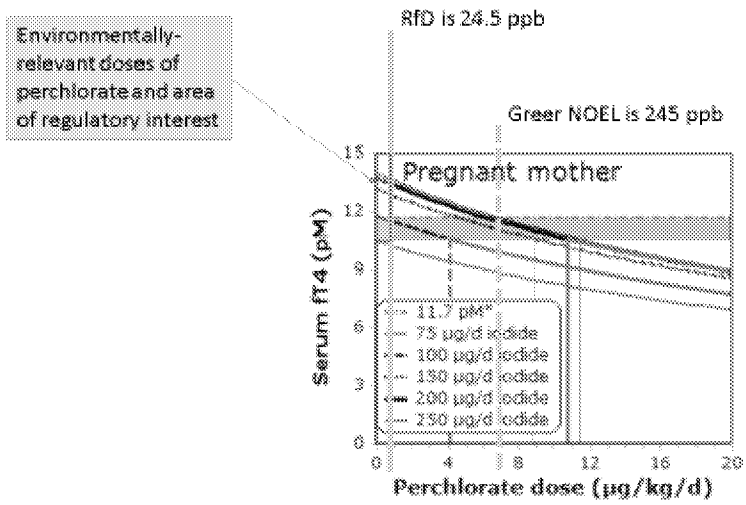

Figure 10. Free T4 (fT4) levels as a function of the perchlorate exposure and dietary iodine ingestion in the gestation ~week 40 pregnant mother and fetus. (Fetus graph not reproduced here as EPA does not report effects. See EPA document for graph.)

FIGURE 1. FIGURE 10 FROM US EPA'S MODEL REPORT REPRESENTING BBDR MODEL OUTPUT FOR PREGNANT MOTHER

Green lines are added to this reprint of the figure to demonstrate the approximate doses for two relevant endpoints. The first is US EPA's Reference Dose which is 0.7 µg/kg-d (24.5 ppb using US EPA standard conversion factors) and the dose for the NOEL in Greer *et al.*, 2002 which is 7 µg/kg-d (245 ppb using US EPA standard conversion factors). Note that the relevant perchlorate water concentrations in drinking water in the US are below 24.5 ppb. The US EPA BBDR model for the pregnant woman focuses on doses considerably higher.

TABLE 2. MATERNAL FT4 (PM) BASED ON IODINE INTAKE AND PERCHLORATE DOSE FROM EPA BBDR MODEL

Perchlorate Dose µg/kg-d	Iodine Intake 75 ug/d	100 ug/d	150 ug/d	200 ug/d	250 ug/d
0	10.46	11.77	13.17	13.74	13.98

4.0 IMPROVEMENTS TO THE US EPA DRAFT BBDR MODELS

This will be the first model used by US EPA to determine an MCLG. The Model is focused on the condition of hypothyroxinemia as an indicator of the potential adverse health effects. This draft model predicts the effects of perchlorate on serum thyroid hormone concentrations in the pregnant and lactating mother exposed to perchlorate in the diet and in infants exposed via ingestion of perchlorate in formula or breast milk.

The model can be improved providing additional support in integrating the model code, increased transparency in the output, and improving the ability of the model to predict both perchlorate and iodine deficiency with no perchlorate. Since not all of the peer reviewers will have modeling experience, they will rely on US EPA to provide the only information on the model and will not conduct an independent assessment.

4.1 BBDR model codes

The BBDR model was developed by integrating PBPK models for perchlorate and iodide with BBDR models for thyroid hormones to predict the effect of perchlorate on the thyroid gland in pregnant women and fetuses, formula-fed and breast-fed infants for the postnatal period from days 7 to 90, as well as lactating women. There were actually two models that were released: the pregnancy model (pregnant woman and fetus) and lactation model (lactating woman and infant).

4.1.1 Instructions are incomplete

We were pleased that US EPA released the code in two languages. We were aware that the manufacturer of acslX, Aegis Technologies, had decided to discontinue the software and no longer provide support as of December 2015. Recognizing this as an issue, as the BBDR model was developed in acslX, US EPA translated the code in to R, a free software platform for statistics. We are familiar with both platforms and have utilized both in this assessment.

The integration of both versions of the code is not straightforward. There are minimal instructions. The acslX code has no instructions included. The R code does have two very brief "README" files,

but requires significant time to download several files, software add-ons, and install the code. This will not be an easy process for the peer reviewers in the limited time.

4.1.2 Model variables and parameters are poorly documented

Once installed and operating, there are issues with the description and documentation of the model parameters. Model variables are poorly documented within the model. For example, M files in aclsX have no references for the basis of the variable. Proper and complete documentation is standard in PBPK modeling and utterly important given the uniqueness of this particular model

Each model (pregnancy and lactation) is broken into a number of subscripts and it is challenging to discern how the subscripts interact (e.g., in which order they are called, and where variable values change), especially when modifying/testing different variable values). Additionally, the code is not provided to produce full tabulated model output (e.g., thyroid hormone levels, serum perchlorate concentrations), and must be added to generate/evaluate this output (e.g., Table 2).

4.1.3 Models require separate input and transfer of data from one model to another

There are two separate models that were provided by US EPA: the pregnancy model (pregnant woman and fetus) and lactation model (lactating woman and infant). The lactation model starts with output from the pregnancy model, so to produce relevant output for the lactating mother/infant, the inputs (e.g., iodide and perchlorate intake) must be checked in each model separately to be sure they are consistent. This takes considerable time and attention and will be difficult for the peer reviewers to do under the limited time constraints.

4.2 Output of model

We note several issues of concern specifically on the model. The models are not dynamic models and are limited by steady-state assumptions, the model includes a lot of uncertainty, and the model cannot accurately model iodine deficiency (with no perchlorate exposure) which is a key component of the overall hypothesis.

4.2.1 Model considers steady state conditions

For a given model run, the model produces output based on iodide and perchlorate doses that remain constant throughout the model run (in units of μg/day for iodide and ng/kg-d for perchlorate). The model thus does not capture the expected variability in input of iodide and perchlorate with daily variations in diet, drinking water ingestion, and supplement intake. Further, for the pregnant woman, input parameters are held constant, corresponding to a single time point during pregnancy (at 40 weeks). The model does not account for the expected variability in biological/physiological parameters (e.g., body weight, body fat percentage, blood volume, daily urine volume) that occur as one advances through pregnancy. Conversely, for the lactating female, some parameters are assumed to change through time (e.g., body weight, percent body fat) while other parameters are held constant (e.g., daily urine volume).

The Report notes this limitation, stating:

> Because the only source of variability evaluated was iodide and perchlorate dietary intake, it is not expected that the model will capture the entire observed variability. Variability in physiological factors, such as urinary excretion rate and body weight, and biochemical factors, such as NIS expression and thyroid hormone synthesis activity, would also have significant effects on the metrics evaluated.

ED_005043_00062728-00104

Of note, US EPA could have considered the parameters probabilistically. For example, the model by Lumen *et al.* (2013) was adapted to include a wider functional range of iodine intake and to model populations using Monte Carlo (Lumen and George, 2016). An adaptation such as this would give greater insight into population variability and would provide a clearer impact of goitrogens.

4.2.2 Model lacks accuracy in predictions

The report section "Model Calibration Results" compares model outputs to literature values for similar populations. In general, the report states that model-predicted concentrations are "within reported values"; however, the report does not indicate that the model was adjusted based on these comparisons. Thus, it does not appear that these data were used to actually "calibrate" the model, i.e., to identify parameters to adjust to improve model accuracy and predictability. No other calibration based on model outputs is described.

The report compares model predictions to literature based values for only a limited number of parameters. The parameters compared to literature based values, and the source of those values, are:

- Urinary iodide for the formula-fed infant (Figure 4, top panel). Data compared are from Gordon *et al.* (2014) and Cao *et al.* (2010).
- Urinary perchlorate for formula-fed infant (Figure 4, bottom panel). Data compared are from Cao *et al.* (2010).
- Urinary iodide for the breast-fed infant (Figure 5). Data compared are from Gordon *et al.* (2014) and Cao *et al.* (2010).
- Urinary perchlorate for the breast-fed infant (Figure 6). Data compared are from Leung *et al.* (2012) and Cao *et al.* (2010).
- Breast milk iodide (Figure 7, top panel). Data compared are from Leung *et al.* (2012).
- Breast milk perchlorate (Figure 7, bottom panel). Data compared are from Leung *et al.* (2012).
- Serum T4 and fT4 for lactating mothers (Figure 8). Data compared are from NHANES.
- Serum T4 and fT4 for breast-fed infants (Figure 9). Data compared are from Cao *et al.* (2010), Leung *et al.* (2012), and Lem *et al.* (2012).

Examination of the cited studies confirms that while predicted model results do fall within the range of cited literature values, in each case, the range of values reported in the cited study is very broad suggesting that the model does not adequately capture all of the sources of variability that can impact these concentrations. Further, these comparisons suggest that predicted serum T4 and fT4 values are within "normal" ranges, even at relatively high perchlorate intake levels and for a range of iodine intake levels.

Cao *et al.* (2010) evaluated 92 full term infants between birth and 1 year of age each seen up to four times, as part of the Study of Estrogen Activity and Development (SEAD). Clinical visits took place at the Hospital of the University of Pennsylvania and the Children's Hospital of Philadelphia. Perchlorate and iodide were measured in 206 urine samples, and fT4 was measured in 50 blood samples. Although the children consumed cow's milk formula, soy formula, or breast milk, no data on concentrations of perchlorate or iodide in formula or breast milk are provided and so comparisons of these data to model results for different assumed iodide intake levels (Figures 4, 5, and 9) are misleading. While Cao *et al.* (2010) do not present individual data values, Figures 4 and 5 plot individual urinary iodide concentrations reported in this study for formula- and breast-fed infants,

ED_005043_00062728-00105

respectively, for ages 0 to 90 days. Cao *et al.* (2010) also present their data in units of μg/g creatinine, not μg/L as in Figure 4. It is unclear how EPA obtained and transformed this data.

Since the figures present results on a log-scale, the true variability of values is not readily apparent. Indeed, urinary iodide concentrations measured in this population vary widely, from approximately 50-7,000 μg/L. For infants from 0 to 15 days of age, measured urinary iodide concentrations range from approximately 20 to 800 μg/L. By comparison, model-predicted urinary iodide concentrations for the breast-fed infant at day 7 range from about 58 to 201 μg/L for a perchlorate dose of 0.1 μg/kg-d and iodine doses ranging from 75 to 250 μg/day. Although model-predicted values are "within the range" of measured values as stated by US EPA, the range of measured values is extremely wide such that these comparisons provide little information about the predictability of the model. Further, these comparisons suggest that since the actual range of urinary iodide in a population is wider than predicted by the model, the model does not adequately capture all of the variability in population characteristics that can lead to widely varying urinary iodide concentrations. Given that Cao *et al.* (2010) did not provide formula or breast milk concentrations of iodine or perchlorate, it is impossible to use the Cao *et al.* data to assess the predictability of the model for specific iodine or perchlorate doses.

Similarly, Figures 4 and 6 plot individual urinary perchlorate concentrations measured in the Cao *et al.* (2010) study (although not presented in the paper) for formula- and breast-fed infants, respectively, for ages 0 to 90 days. Based on the figures, urinary perchlorate concentrations measured in these populations vary within a more narrow range than do iodide concentrations, from approximately 0.3-5.5 μg/L for formula fed infants and 0.05-12 μg/L for breast-fed infants. For infants from 0 to 15 days of age, measured urinary perchlorate concentrations range from approximately 0.3-5.2 μg/L for formula fed infants and from 0.08-4 μg/L for breast-fed infants. By comparison, model predicted urinary perchlorate concentrations for the breast-fed infant on day 7 at an iodine dose of 150 μg/day range much more widely, depending on the assumed perchlorate input: these estimates are approximately 0.09 μg/L for a perchlorate dose of 0.001 μg/kg-d, 0.9 μg/L for a perchlorate dose of 0.01 μg/kg-d, 9.8 μg/L for a perchlorate dose of 0.1 μg/kg-d, and 128 μg/L for a perchlorate dose of 1 μg/kg-d.

While Figure 9 shows that fT4 serum concentrations in breast-fed infants measured in Cao *et al.* (2010) ranged from about 5 to 22 pM, the geometric mean concentration of serum fT4 in breast-fed infants reported in the Cao *et al.* (2010) paper was much higher, or 42.5 pM (3.3 ng/dL) (95% UCL = 34.7-51.5 pM) (individual values are not reported). The reason for this discrepancy is not provided. By comparison, model predicted values were much different: for 7-day old breast-fed infants with a perchlorate dose of 0 μg/kg-d, predicted fT4 levels range from 20.5 to 26.4 pM for iodine intakes ranging from 75 to 250 μg/day, and for 7-day old breast-fed infants with a perchlorate dose of 1 μg/kg-d, predicted fT4 levels range from 19.9 to 25.6 pM for iodine intakes ranging from 75 to 250 μg/day. For 90-day old breast-fed infants with a perchlorate dose of 0 μg/kg-d, predicted fT4 levels range from 21.6 to 25.6 pM for iodine intakes ranging from 75 to 250 μg/day, and for 90-day old breast-fed infants with a perchlorate dose of 1 μg/kg-d, predicted fT4 levels range from 21.0 to 25.4 pM for iodine intakes ranging from 75 to 250 μg/day. The authors note that, for the 50 cases where both urinary perchlorate and serum thyroid hormone concentrations were available, "there was no significant association between TSH or T4 and perchlorate, thiocyanate and nitrate exposure."

Gordon *et al.* (2014) evaluated 95 breast-fed and/or formula-fed infants less than 3 months of age in the Boston area. Iodide concentrations were measured in single spot urine samples. Like the Cao *et al.* (2010) study, no data were reported on iodine concentrations in breast milk or formula, and urinary iodine concentrations measured widely: concentrations of urinary iodide for the full group

ED_005043_00062728-00106

ranged from 40-897.5 μg/L with a median of 197.5 μg/L. In breastfed infants (n = 39), the median urinary iodine concentration was 203.5 μg/L with a range from 61.5-395.5 μg/L, and in formula fed infants (n = 44), the median urinary iodine concentration was 182.5 μg/L with a range from 40-897.5 μg/L. Urinary iodine concentrations in infants who received mixed input from both breast milk and formula (n=10) were intermediate: the median was 197.8 μg/L, and the range was 123-592.5 μg/L). By comparison, model predicted values of urinary iodide for the breast-fed infant at day 30 range from about 65 to 184 μg/L for a perchlorate dose of 0.1 μg/kg-d and iodine doses ranging from 75 to 250 μg/day. The predicted urinary iodide concentration at the intermediate iodine dose of 150 μg/day was 129 μg/L. For this group, the model-predicted values tend to be substantially lower than the measured values; as above, the much wider range of measured values suggests that the model does not adequately capture the variability in population characteristics that can lead to widely varying urinary iodide concentrations. Again, while the model-predicted values are "within the range" of measured values; however, the range of measured values is extremely wide, indicating that the model does not adequately capture the variability in population characteristics that can lead to widely varying urinary iodide concentrations.

Leung *et al.* (2012) evaluated concentrations of iodide and perchlorate in breastmilk, maternal urine, and infant urine in 64 mother/infant pairs. The median iodide concentration was 45.6 μg/L (range 4.3-1,080 μg/L) in breastmilk, 101.9 μg/L (range 27-570 μg/L) in maternal urine, and 197.5 μg/L (range 40-785 μg/L) in infant urine. The median perchlorate concentration was 4.4 μg/L (range 0.5-29.5 μg/L) in breastmilk, 3.1 μg/L (range 0.2-22.4 μg/L) in maternal urine, and 4.7 μg/L (range 0.3-25.3 μg/L) in infant urine. By comparison, model predicted urinary iodide concentrations for the breast-fed infant at day 7 range from about 58 to 201 μg/L for a perchlorate dose of 0.1 μg/kg-d and iodine doses ranging from 75 to 250 μg/day. It is unknown what the source of perchlorate exposure and the daily perchlorate dose was in the population evaluated by Leung *et al.* (2012). By comparison, model-predicted urinary perchlorate concentrations for the breast-fed infant on day 7 at an iodine dose of 150 μg/day are approximately 0.09 μg/L for a perchlorate dose of 0.001 μg/kg-d, 0.9 μg/L for a perchlorate dose of 0.01 μg/kg-d, 9.8 μg/L for a perchlorate dose of 0.1 μg/kg-d, and 128 μg/L for a perchlorate dose of 1 μg/kg-d.

Again, EPA uses the imprecise phrase "within the range" to describe the model results compared to measured values reported by Leung *et al.* (2012). The range of measured values is very wide indicating that the model does not adequately capture the variability in population characteristics that can lead to widely varying urinary concentrations. Of interest, Leung *et al.* (2012) indicate that at these widely varying input levels, "There were no correlations between infant TSH or FT4 and iodine, perchlorate, and thiocyanate levels in breastmilk, maternal urine, and infant urine." Further, "In multivariable analyses, perchlorate and thiocyanate levels in breastmilk, maternal urine, and infant urine were not significant predictors of infant TSH or FT4." Finally, the authors note:

> Boston-area mothers and their breastfed infants are generally iodine-sufficient. Although environmental perchlorate and thiocyanate are ubiquitous, these results do not support the concern that maternal and infant environmental perchlorate and thiocyanate exposures affect infant thyroid function.

Thus, comparison of model outputs to these data, and the assertion that model outputs fall within the range of measured values, suggests that the model output is within normal population values.

Lem *et al.* (2012) measured fT4 and total T4 (TT4) in 512 children ages 0-18 years, to determine age-specific thyroid hormone reference ranges. The study does not report perchlorate or iodide intake levels or concentrations in any medium (e.g., urine or breast milk). Summary data are provided for

infants at 1 week, 1 month, and 3 months. As shown in Figure 9, model-predicted serum TT4 and fT4 concentrations in infants are within the reference ranges reported in Lem *et al.* (2012). However, the reference ranges are very wide—for TT4, the mean ranged from 132.6 nM at 1 week (2.5%ile = 75.9 nM, 97.5%ile = 239.1 nM) to 135 nM at 3 months (2.5%ile = 82.3 nM, 97.5%ile = 227.3 nM). For fT4, the mean ranged from 0.022 nM at 1 week (2.5%ile = 0.012 nM, 97.5%ile = 0.053 nM) to 0.020 nM at 3 months (2.5%ile = 0.013 nM, 97.5%ile = 0.037 nM). Lem *et al.* (2012) does not distinguish between breast-fed and formula fed infants. US EPA states, "Model-predicted concentrations of T4 and fT4 in both lactating mothers and breast-fed infants were within the range of literature reported values." However, given the wide reference ranges, this is not surprising. Model-predicted serum fT4 concentrations at a perchlorate intake of 0 μg/kg-d are highly dependent on assumed iodine intake levels (ranging from 0.020 nM at an iodine dose of 75 μg/d to 0.026 nM at 250 μg/d for the 7-day old infant and from 0.022 nM at 75 μg/d to 0.026 nM at 250 μg/d for the 90-day old infant). Further, even at a perchlorate dose up to 8 μg/kg-d, for iodide doses of 100 μg/d and above, predicted fT4 levels at 3 months exceed the mean reference value reported in Lem *et al.* (2012) for this age (0.020 nM).

The model sets the prediction of fT4 as a constant proportion of the TT4 concentration. Specifically, the model assumes that the fT4 concentration is 0.0001 times the TT4 concentration for the lactating mother, 0.00009 times the TT4 concentration for the pregnant mother, and 0.00017 times the TT4 concentration for the infant. These values are based on literature data. However, these fixed values do not capture the variability that can be associated with these estimates.

Some model parameters or compartments are modeled differently between the pregnant and lactating woman models, and an explanation of these differences or their impact on model predictions is not provided. For example, the pregnancy model assumes a value for the serum binding constant for perchlorate (VmaxC_Bp) of 585 ng/hr/kg (5.9 nmol/hr/kg$^{0.75}$), whereas the lactating model assumes a value of 1230 ng/hr/kg (12.4 nmol/hr/kg$^{0.75}$). In another example, the algorithm in the pregnant woman model for calculating plasma concentrations of iodide and perchlorate (RAplasma_i and RAplasma_p, respectively) includes an elimination term, whereas the lactating model does not.

4.2.3 Model cannot model iodine deficiency accurately

A fundamental concept in modeling the key mechanism of action of perchlorate (and other goitrogens) is to predict iodine deficiency without the influence of any other agents. Without the ability to model iodine deficiency, US EPA cannot propose that a particular agent can cause "iodine deficiency." Modeling iodine deficiency is necessary to ensure the utility of the BBDR models. US EPA did not develop a model that can be used to model iodine deficiency. Further complicating the model by adding in chemical exposure is akin to building on a weak foundation.

4.2.4 Lactating mother is more sensitive to iodine deficiency than pregnant

US EPA notes that the lactating mother is more sensitive to iodine deficiency:

> Some further analysis is needed to understand why, even with an iodine intake of 250 μg/d, the lactating mother is so much more sensitive to perchlorate than the formula fed infant.

Based on the output of the model and US EPA's defined hypothyroxinemia range, this is what is suggested. However, there are several important issues to consider. First, there are no studies that support greater effect of perchlorate on the lactating woman. Second, there are no studies to support an adverse effect of perchlorate on a lactating woman or her breast-fed child. Third, if we were to assume that the lactating woman does have decreased fT4 caused by a given perchlorate dose while her infant does not, the effect of low fT4 has different effects on an adult. Neurodevelopmental

outcomes are not a potential endpoint for exposure in a fully grown adult. Thus, if US EPA chooses to evaluate the lactating woman in a later assessment, they must define a different adverse effect that is relevant to her versus her infant.

4.2.5 Model results with doses lower than 1 μg/kg-d

If we do focus in on the results from the model that are below 1 μg/kg-d and results with fT4 levels greater than the 2.5th percentile (based on US EPA's hypothyroxinemic range), then for nearly all iodide levels in all life stages, the model does not predict hypothyroxinemia due to perchlorate exposure. The exception is the pregnant woman consuming 100 μg/d of iodine with perchlorate doses greater than 0.3 μg/kg-d.

In the lactating woman, US EPA notes that even without perchlorate, their model predicts hypothyroxinemia:

> Thus, the iodide levels and thyroidal stores for infants whose mothers ingest only 100 μg/d iodine are already compromised (though they may be sufficient for healthy development in the absence of perchlorate), hence these infants are more sensitive to any further decrease due to inhibition by perchlorate (Figure 13).

Taken together, US EPA's own data suggest that perchlorate exposure is not predictive of hypothyroxinemia (See Figure 1).

5.0 ISSUES OVERARCHING THE REPORT AND MODELS

There are several conceptual issues that are not specific to the Report or the Models, but are critical in consideration of the output and how the output will be used. Hypothyroxinemia is not an adverse effect, but since the current model cannot be used to evaluate changes in TSH, it is being considered the endpoint of concern. The model predictions are also inconsistent with animal data and the known MOA of perchlorate and other goitrogens.

5.1 Hypothyroxinemia as an endpoint

Diagnoses based on thyroid hormone measures are well-defined clinically. Overt hypothyroidism is considered an adverse effect and, if it occurs in a pregnant woman or infant, may affect the developing brain resulting in permanent impairment. Hypothyroidism is defined as sustained elevated TSH and low fT4. The NRC recognized hypothyroidism as the first adverse effect on the dose-response continuum (NRC, 2005). Subclinical hypothyroidism is elevated TSH with normal levels of fT4. Hypothyroxinemia is defined as low fT4 with normal levels of TSH.

US EPA has chosen to use hypothyroxinemia, not hypothyroidism, as the critical effect. The BBDR model can only predict levels of TT3 and TT4. Although fT4 is not mechanistically modeled, US EPA uses a fraction of TT4 to define fT4 levels.

5.1.1 US EPA's derived reference range for fT4

Although there is a reference range for TSH levels in different stages of pregnancy and in infancy, an analogous reference range does not exist for fT4. The reason is that different laboratories have variations in techniques and populations that make direct comparisons impossible. Therefore, in general, a laboratory will consider a cutoff for "low" or "high" based on the percentile in the batch it is testing. This cutoff is commonly the lowest 2.5th percentile, 5th percentile, or 10th percentile. There is no recommendation by any authoritative medical body on the appropriate cutoff.

ED_005043_00062728-00109

In its derivation of a provisional reference range, US EPA has arbitrarily chosen ranges with varying methods and confusing variation. For the pregnant women, US EPA describes a process for normalizing several studies in the literature although this methodology has not been verified or peer reviewed prior to the current review. For infants, values from Lem et al. (2012) were used. Possibly due to the variations in choosing these provisional ranges by life stage, there are discrepancies that are not explained. For example, it is difficult to understand why the 7-day old formula-fed infant has the 10th percentile fT4 at 16.9 pM while the 7-day old breast-fed infant 17.8 pM. The biological needs of a 7-day old infant should be independent of the feeding source.

5.1.2 Hypothyroxinemia is not an adverse effect

Transient hypothyroxinemia is not uncommon in pregnant women and severely premature infants (born at less than 28 weeks). In an individual, hypothyroxinemia is not considered adverse. The American Thyroid Association, American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics do not recommend treatment for hypothyroxinemia. The Endocrine Society suggests best judgement by the treating physician, however, does not recommend treatment in third trimester women (Furnica *et al.*, 2015).

Hypothyroxinemia as an endpoint to measure is questionable, particularly in pregnancy. There is a necessary rise in TT4, but also increased binding due to TBG, HCG, and other serum proteins. This results in hypothyroxinemia (low fT4), but no change in circulating T3 levels with T3 being the active hormone. It is hypothesized that hypothyroxinemia is an adaptive response by the body to maintain adequate hormone level (Furnica *et al.*, 2015).

US EPA may not use hypothyroxinemia as the adverse effect, per se. US EPA recently stated:

> EPA is considering deriving a perchlorate MCLG by linking BBDR model output to alterations in thyroid hormone status that result in alterations in neurodevelopment. (see 81 FR 10617, March 1, 2016)

There are studies that suggest an association between first trimester hypothyroxinemia and adverse neurodevelopmental outcomes in offspring. The literature on these outcomes is mixed. Most of the studies have small study populations and the inability to control for confounders over the study period (often years). Interventional studies have also reported that treatment of the mother with synthetic thyroxine normalizes thyroid hormone levels, but does not improve outcome compared to untreated (Lazarus *et al.*, 2011). Importantly, these studies all evaluate hypothyroxinemia in the first trimester with outcomes at two to three years of age. The BBDR model predicts hormone levels in the late stage (gestation week 40) pregnant woman.

Importantly, even if there were a high quality study that was able to demonstrate a causal relationship between first trimester hypothyroxinemia and adverse neurodevelopmental outcomes in offspring, the model is based on late-term (gestation week 40) pregnant women. The output from this model cannot be associated with this neurodevelopmental outcome.

5.2 The model does not account for compensatory mechanisms

The HPT axis of the human body is a dynamic system with both positive and negative feedback controls. This allows the body to tightly maintain availability of thyroid hormone levels to accommodate developmental needs or changes in diet or health. Both high and low levels of thyroid hormone can result in an adverse effect. The body is able to homeostatically regulate thyroid hormone, even in during periods of decreased iodine intake, by several different mechanisms. For example, decreased thyroid hormone would trigger TSH release from the pituitary gland which

ED_005043_00062728-00110

would increase NIS activity, stimulate iodination of thyroglobulin (Tg), stimulate organification of T4 and T3, increases turnover of Tg to make more thyroid hormone, and increase secretion of thyroid hormone to the circulation. The model by Lumen and George (2016) does empirically include homeostatic mechanisms.

The BBDR model does not include any compensatory mechanisms, such as TSH feedback or increase in NIS activity. US EPA has stated that

> …it is assumed that thyroid conditions occur for the fT4 levels between the 10th and 90th percentile of the entire population in a given life stage, and that hypothyroxinemia occurs for fT4 levels between the 2.5th and 10th percentile for the entire population. When fT4 falls below the 2.5th percentile for the entire population in a life stage, it is assume that TSH levels would be sufficiently elevated to trigger hormonal feedback, invalidating the model predictions.

Presumably, until the serum levels of fT4 fall below the 2.5th percentile, no change in TSH would be expected. Although there is no evidence to suggest this is correct, this suggests a more appropriate measure of adverse effect is below 2.5th percentile. However, even if US EPA changes its level to evaluate to 2.5%ile, this is still only a surrogate for change in TSH. And changes in TSH are not necessarily adverse unless sustained increased TSH is coupled with decreased fT4 (NRC, 2005).

Since the model does not include algorithms for calculating serum TSH levels, it cannot reliably predict thyroid hormone impacts for iodine intakes representative of iodine deficiency. When predicted fT4 levels fall below the "hypothyroxinemic range" in a functioning biological system, TSH would be expected to be elevated resulting in a feedback loop that would attenuate any effects. The model does not include this feedback loop. Thus, when model figures show predicted fT4 levels that fall below the hypothyroxinemic range, values are shown in grey to emphasize the uncertainty of these results.

5.3 Animal data on neurodevelopmental outcomes

There are several animal studies evaluating perchlorate exposure during pregnancy and neurodevelopmental outcomes (Bekkedal *et al.*, 2000; York *et al.*, 2001; York *et al.*, 2004; York *et al.*, 2005). The endpoints reported for each study are summarized in Table 3. These were controlled animal experiments with doses ranging from 0 (controls) to 30 mg/kg-d (30,000 µg/kg-d or 1,050,000 ppb), dosed orally during gestation. These studies all report no significant changes in the developmental endpoints measured.

5.4 Model predictions are inconsistent with the known MOA

The MOA of perchlorate is well understood and is not contested. Perchlorate affects the thyroid by competitively inhibiting iodide uptake to the thyroid through interaction with the sodium iodide symporter (NIS). This inhibition is reversible and not considered adverse. With sustained and significant inhibition—estimated to be about 70% inhibition for several months or more (NRC, 2005)—hypothyroidism could occur. Changes in thyroid hormone cannot occur without IUI; however, changes in thyroid hormones are not an inevitable consequence of IUI, that is, with cessation of exposure, no adverse health effects would occur.

The threshold at which radioactive iodide uptake (RAIU; the measure of IUI) occurs has also been determined in several clinical studies. A No Observable Effect Level (NOEL) for this nonadverse effect has been reported at 0.007 mg/kg-d (Greer *et al.*, 2002) and 0.04 mg/kg-d (assuming a 70 kg body weight; Braverman *et al.*, 2006; Lawrence *et al.*, 2001). The study by Greer *et al.* (2002) was

ED_005043_00062728-00111

TABLE 3. ANIMAL STUDIES ON NEURODEVELOPMENT AND ENDPOINTS REPORTED

Study	Doses	Endpoint	Result
Bekkedal *et al.*, 2000	0, 0.1, 1.0, 3.0, 10 mg/kg-d	General locomotor activity	No significant change in general locomotor activity due to prenatal and neonatal perchlorate exposure
York *et al.*, 2001	0, 0.3, 3.0, 30 mg/kg-d	F1 generation brain weights	No significant changes in developmental parameters were observed
York *et al.*, 2004	0, 0.1, 1.0, 3.0, 10 mg/kg-d	Juvenile brain weights, morphometry, and neuropathology (PND 12); Adult regional brain weights (PND 89), morphometry, and neuropathology; Passive avoidance and water maze testing, motor activity and auditory startle habituation	No effect on body weights, feed consumption, clinical observations, or sexual maturation of pups No behavioral effects as evaluated by passive avoidance, swimming water maze, motor activity, and auditory startle Significant decrease in follicular lumen diameter at ≥1 mg/kg-d (males)
York *et al.*, 2005	0, 0.1, 1.0, 3.0, 10 mg/kg-d	Motor activity (PNDs 14, 18, and 22) and juvenile brain weights, neurohistopathological examinations, and regional brain morphometry (PNDs 10 and 22)	Authors conclude that the NOAEL for maternal toxicity was greater than 10 mg/kg-d and the NOAEL for pup toxicity was 0.1 mg/kg-d based on the thyroid morphometric and histopathologic findings

the lowest reported NOEL for RAIU and the higher doses of 0.02, 0.1, and 0.5 mg/kg-d all resulted in changes in RAIU. This was supported by a separate clinical study reporting significant RAIU with exposure to 0.14 mg/kg-d (Lawrence *et al.*, 2000). None of these studies reported changes in thyroid hormones in any dose tested.

It has been suggested that these studies are in healthy adults and pregnant women or children may represent populations unusually sensitive to goitrogenic effects. However, there is nothing to support this hypothesis; rather, the NIS is highly conserved among species and the rate of uptake, affinity, and residence time of perchlorate or iodide is unlikely to vary for pregnant women or children.

The model predicts that perchlorate can change fT4 levels at doses lower than the threshold for IUI for pregnant and lactating women (See Figure 2). For example, the doses of perchlorate for the pregnant woman consuming 100 μg/d of iodide are listed in Table 2 (section 3.3 above). Based on this, there is a 2% decrease in fT4 levels occurring with an increase in perchlorate dose from 0 to 0.7 μg/kg-d. However, this is all 10-fold below the known NOEL for IUI of 7 μg/kg-d. This clearly is inconsistent with the clinical literature. In another example, the model predicts changes in fT4 in the lactating woman with any addition of perchlorate. NRC (2005) estimated that approximately 75% inhibition of iodide uptake daily (a non-adverse precursor to thyroid hormone changes) would be necessary to cause any adverse effect. US EPA's model predicts that 75% iodide uptake would require a dose of over 500 μg/kg-d in a lactating woman (Figure B-7 in the Report). A dose of 500 μg/kg-d has not been reported to cause changes in thyroid hormone (Greer *et al.*, 2002; Braverman *et al.*, 2006).

Second, the model's affinity constant is calibrated using the data from Greer *et al.* (2002). US EPA reports that the model accurately predicts no change from baseline in RAIU with exposures up to

ED_005043_00062728-00112

0.007 mg/kg-d. Thus, the model itself predicts changes in thyroid hormone without change in IUI. This cannot occur given the known MOA.

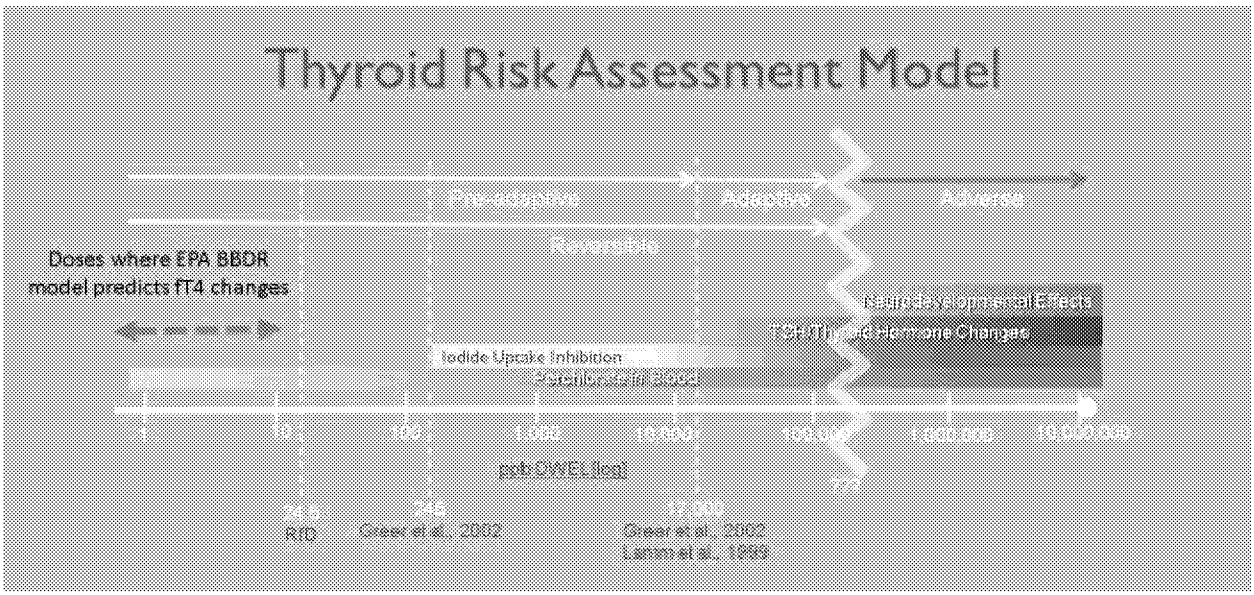

FIGURE 2. REPRESENTATION OF THE DOSE-RESPONSE CURVE (IN WATER CONCENTRATION USING STANDARD US EPA CONVERSION FACTORS) FOR PERCHLORATE

Summary of the dose-response of perchlorate on thyroid parameters and neurodevelopmental effects in offspring based on over 60 years of animal, clinical, and epidemiological data and reviews and consensus from multiple authoritative bodies. The three vertical white hashed lines represent the EPA Reference Dose (based on 0.7 µg/kg-d), the NOEL dose (7 µg/kg-d based on Greer *et al.* (2002)), and the high dose in Greer *et al.* (2002) where no change in thyroid hormone occurred (500 µg/kg-d). EPA's BBDR model predicts changes orders of magnitude lower than demonstrated in clinical studies and is contrary to the known mechanism of action (green arrow).

5.5 Daily background goitrogen load is not considered

Other chemicals have the same MOA as perchlorate and are found at levels in the diet that are greater than perchlorate, namely nitrate and thiocyanate. Cumulative risk assessment is commonly used by US EPA when evaluating pesticides, but has not been applied under the SDWA. The total effect on IUI can be estimated using perchlorate equivalence. The equivalence is based on affinity of the anion to the symporter. The study to determine equivalence has been conducted in cell culture using human NIS transfected into the cells (Tonacchera *et al.*, 2004). This is a reliable method that has been used for decades in medical pharmacology. Although some criticize cell culture as a substitute for human studies generally, in this case, the relative interaction between the anion and the receptor is better quantified *in vitro*. Additionally, multiple animal studies have reported similar potencies of the three goitrogens (Wyngaarden *et al.*, 1952; Wyngaarden *et al.*, 1953). Willemin and Lumen (2016) also published the development of a PBPK model to evaluate the dose-response of thiocyanate; thus, it is possible to increase the utility of the Model by introducing additional chemicals.

US EPA's Office of the Inspector General (OIG) released a report in 2010 recommending and demonstrating use of cumulative risk assessment for perchlorate, nitrate, and thiocyanate. They also included iodine deficiency as a thyroid stressor. The report noted that perchlorate accounted for less than 1% of total goitrogen load on the thyroid and regulation of this chemical in isolation would produce no benefit to public health. Other studies have also reported the same contribution of perchlorate to total goitrogen load (Tarone *et al.*, 2010; Bruce *et al.*, 2013).

Relatedly, the studies used to calibrate the model did not consider background doses of goitrogens. Only two studies were used to calibrate infant perchlorate, TT4, and fT4: Cao *et al.* (2010) and Leung *et al.* (2012). Cao *et al.* (2010) measured infant urinary nitrate, thiocyanate, and perchlorate, and reported geometric means and 95% confidence intervals for urinary nitrate of 95 μg/g creatinine (69-131) and urinary thiocyanate of 1000 μg/g creatinine (760-1320). In Leung *et al.* (2012), perchlorate, thiocyanate, and iodine were measured. For thiocyanate, they report thiocyanate levels of 373.5 μg/L (31.1–2420 μg/L) in maternal urine, and 193 μg/L (21.7–1880 μg/L) in infant urine (Leung *et al.*, 2012). The range that these two studies report spans two orders of magnitude suggesting significant variability in this study population. As a point of reference, NHANES 2011-2012 reports a geometric mean urinary thiocyanate and 95% confidence interval of 1133.5 μg/L (1002.1–1282.2) for females age 20 and older (Jain, 2016).

Thus, US EPA's calibration based on studies where the impact of another chemical with the same MOA also may be contributing to data reported is neither described as a limitation, nor considered in the assessment.

6.0 CONCLUSION

We have several scientific issues with the approach US EPA is taking to evaluate whether perchlorate should be regulated and at what level. In general we agree with the approach and process US EPA is taking as long as the process is transparent and science-based. We agree on the use of a BBDR or PBPK/PD model for the assessment of relevant physiological parameters that can inform US EPA on the possible health impact of perchlorate exposure. We agree that it must be scientifically defensible and utilize the best available science.

We think the US EPA Draft Model Report and BBDR Model Codes require considerable improvement to be useful for regulatory purposes. The Model Report can be improved with a more systematic approach and greater transparency. The Agency's cited literature will benefit by a complete literature review to support its conclusions.

The Model code must have greater transparency and resolve any inconsistencies. US EPA's choice of several parameters used in the model are not well supported or defined within the model code. The models are extremely difficult to set up and run. We have concern about the constraints of time on the peer reviewers to implement and critically review the model.

Finally, we have several overarching concerns that US EPA could address that would greatly assist a scientific peer review. The endpoint of hypothyroxinemia, despite the US EPA's recent SAB review, is not a scientifically robust endpoint for evaluation and other thyroidal parameters are necessary to determine an adverse effect. As hypothyroxinemia is not an adverse effect and US EPA has suggested it would relate this data to neurodevelopment in offspring, releasing any documentation related to the application of the model to neurodevelopmental outcomes is necessary. A full understanding of the model is contingent on understanding its intended use. Releasing this data allows for an understanding of the level of sensitivity required of the model. Finally, we do not understand how the peer reviewers will have the ability to conduct a thorough review given the limited time frame. We appreciate the additional 10 days, however, that still is insufficient to address the thoughtful and scientific approach one needs to evaluate any BBDR model.

RE: PERCHLORATE CHARGE QUESTIONS

In response to the Federal Register Notice [81 FR 67350 (September 30, 2016)] and on behalf of the Perchlorate Study Group (PSG),[1] Intertox is pleased to submit comments regarding the charge questions.

Given that this is the first time EPA will develop a Maximum Contaminant Level Goal (MCLG) using Biologically Based Dose Response (BBDR) modeling and that the BBDR is complex, novel and potentially controversial, and will be influential, the PSG is committed to assisting EPA in its goal to use the best available science. The PSG has worked with EPA for more than 15 years to provide scientific information to derive and adhere to the basic standards of quality, objectivity, utility and integrity. It is with this spirit, Intertox provides comments on the peer review.

According to EPA's Peer Review Handbook (2015), there are two types of questions for an effective peer review. The first identifies technical and scientific issues on which the Agency would like feedback. The second invites broad evaluation of the overall work product.[2]

The EPA's charge questions are found here. Seven questions are included in the Draft Charge Questions.

Broad Evaluation Type Questions / Comments

None of EPA's seven listed charge questions addresses a broad evaluation of the BBDR work product and instead all questions listed are technical. The noticeable absence of these broader questions represents a substantial gap in the rigor of the peer review. The Draft Charge Questions would benefit greatly by the evaluation of this specific model for the purpose it is used.

One of the overarching concerns about a proper evaluation of a complex model is the magnitude of material a peer reviewer must go through, particularly given that most of the interim peer reviewers have no demonstrated PBPK/BBDR modeling experience. For example, there are two distinct models, each of which has thousands of lines of code and more than 500 variables. The model code was provided for use on two software platforms; however, one of these is no longer available, a scenario which further limits rigorous review of the model.

The peer reviewers should be asked to comment on the duration of time allowed for review as well as the adequacy of resources provided to review the literature database for perchlorate. We are concerned that EPA did not provide adequate time to conduct a comprehensive review of this model.

---

[1] *The Perchlorate Information Bureau is supported by Aerojet Rocketdyne, American Pacific Corporation, Lockheed Martin and Orbital-ATK. These companies have worked cooperatively with the U.S. Environmental Protection Agency to increase scientific and medical understanding of perchlorate's risk to human health.*

[2] https://www.epa.gov/sites/production/files/2015-10/documents/epa_peer_review_handbook_4th_edition_october_2015.pdf

ED_005043_00062728-00118

It would be beneficial for peer reviewers to be given access to, and encouraged to read, the Agency's *Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by the Environmental Protection Agency*.[3] It would help the peer reviewers to understand how important data quality is to the Agency and provide guidance on addressing the charge questions it raises.

When a charge question asks, for example, "Does the developed model structure adequately and accurately describe the physiology…," what is meant by the term "adequately"? It would help the peer reviewers to understand the level to which they need to evaluate the model. There are many examples of these ambiguous phrases throughout the charge questions. Such undefined terms make it difficult for any peer reviewer to provide a consistent and thorough standard of assessment.

It is unclear why EPA is focused on the pregnant woman and fetus, lactating woman, and infant in exclusion of other life stages. Giving scientific rationale for this policy decision will be useful to the peer review panel as well as the general public. We note that using the results of the Agency's model to support this conclusion is insufficient evidence, as *the model itself* is at issue. Citing empirical evidence published in peer reviewed studies that directly compare adverse effects in these three life stages is the appropriate support.

Given the robust dataset for perchlorate, the Agency can also include a number of secondary sources of information from authoritative bodies should they need more information to address their questions. Notable examples that should not be overlooked include: National Research Council's 2005[4] evaluation of perchlorate and ATSDR's 2010 Toxicology Profile for perchlorate.[5]

Technical and Scientific Type Questions / Comments

Regarding the technical questions, there are topics EPA could expand on in its charge questions in order to ensure that the BBDR model is able to predict the physiology and pharmacology of perchlorate at low environmental doses. We have provided recommendations below:

- *Hypothyroxinemia as a clinical endpoint*. A clinician would test an individual for TSH and not necessarily test for free T4; additionally, hypothyroxinemia is not necessarily an adverse effect in a pregnant or lactating woman; to the point, the American Thyroid Association recommends *not* treating hypothyroxinemia. In the infant, hypothyroxinemia is also not recognized as an adverse effect that warrants treatment and there are no reference levels for this in infants. Is the model accurate to make predictions on health outcomes if the only output is fT4 (and total T4) rather than other relevant thyroid hormone parameters (i.e., TSH)? Explain the scientific support for only using fT4 and provide strong support for the exclusion of the other thyroid markers. The EPA is not a medical organization and the model developers are not clinicians, yet the output and interpretation of the model is to define disease. Does this model accurately predict disease in either the individual or a hypothetical population?
- *Exposure to other goitrogens*. EPA Office of Inspector General (OIG) has demonstrated that perchlorate accounts for less than 2% of the total dietary goitrogen load on a daily basis. How should the peer reviewers reconcile the fact that this model does not include nitrate and thiocyanate (as a minimum) in the model? How do peer reviewers assess the ability for the model to predict adverse outcomes on thyroid hormones given this limitation? Given the pharmacology and toxicology background of perchlorate and other goitrogens, can the model

[3] https://www.epa.gov/sites/production/files/2015-08/documents/epa-info-quality-guidelines.pdf
[4] https://www.nap.edu/catalog/11202/health-implications-of-perchlorate-ingestion
[5] https://www.atsdr.cdc.gov/ToxProfiles/tp.asp?id=895&tid=181

ED_005043_00062728-00119

be further enhanced scientifically in a way that would improve the prediction capability?

- *Doses evaluated are not environmentally relevant.* There are no studies that demonstrate that perchlorate causes hypothyroxinemia in pregnant women, lactating women, or infants at any dose. Consider the doses in EPA's supporting document:
  - "…lactating mothers were predicted to become hypothyroxinemic or hypothyroid at 23 perchlorate exposures below 20 µg/kg/d, even with daily iodine intakes of 250 µg/d." The dose noted (20 µg/kg/d) would be equivalent to a water concentration of 746 ppb, assuming a body weight of 74.6 kg as EPA did in the BBDR model and a drinking water intake rate of 2 L every day).
  - "…the mother stays within the reference range during both pregnancy and lactation as long as perchlorate 14 exposures are below 4 µg/kg/d." Using the same assumptions, the dose of 4 µg/kg/d is equivalent to a water concentration of 149 ppb.

  The model does not predict a linear dose-response relationship. How do responses at high doses relate to doses EPA is considering for regulation? How does EPA reconcile that the doses in clinical studies are orders of magnitude higher than the doses that the model is being asked to use to predict fT4?
- Model predictions are not consistent with the known mechanism of action (MOA). The MOA for perchlorate has been well-recognized and undisputed for decades; that is, perchlorate reversibly blocks iodide uptake (iodide uptake inhibition; IUI) to the thryroid which, if significant (~75% IUI; NRC, 2005) and sustained for months, could result in a decrease in thyroid hormones (e.g., fT4). IUI is a non adverse effect and a clear precursor to an actual adverse effect; the accepted No Observable Effect Level (NOEL) for IUI is 7 µg/kg-d (Greer et al., 2002). Importantly, no other effects occur unless IUI occurs first. EPA should ask the peer reviewers to consider why its model predicts changes in fT4 at doses lower than those it predicts changes in IUI (via RAIU) and the recognized threshold for IUI in the literature.
- *Biological compensation and homeostasis.* What is the scientific assessment of the degree that the model incorporates homeostatic mechanisms? For example, what would the impact on the model be if it included up-regulation of the Sodium-Iodine Symporter?
- *Prediction of steady state is unrealistic.* Iodine and perchlorate intake fluctuate daily. What is the impact of the model output if the dose of perchlorate is steady-state versus the normal variable consumption of food and water?

Thank you for the opportunity to provide these comments.

Sincerely,

Richard C. Pleus, PhD

RE: PERCHLORATE PEER REVIEW

In response to the Federal Register Notice [81 FR 67347 (September 30, 2016)] and on behalf of the Perchlorate Study Group (PSG)[1], Intertox is pleased to submit comments regarding the interim list of peer reviewers. We appreciate that EPA has opted to hold two peer reviews, the first for the Biologically Based Dose Response (BBDR) model and the second to evaluate the implementation of the model results to derive a Maximum Contaminant Level Goal (MCLG). Given that this is the first time that EPA will develop a MCLG using BBDR modeling, the PSG is committed to assisting EPA, as the PSG has for over 15 years, to ensure that the information it disseminates adheres to the basic standards of quality, objectivity, utility, and integrity. It is in this spirit that Intertox provides comments on the interim list of peer reviewers.

Given the compressed time frame for public comment, we have not attempted to evaluate or recommend individual peer reviewers. Instead, we offer general observations that we hope will add value as you develop your process.

Comment 1

Standards of information quality, the assessment factors, and guidelines for peer reviewers would assist the peer reviewers in developing the most reliable assessment for the Agency. These are key documents for the peer review process and provide a level of transparency in the quality the Agency seeks.

- Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by the Environmental Protection Agency (EPA Information Quality Guidelines).
- A Summary of General Assessment Factors for Evaluating the Quality of Scientific and Technical Information
- This 4th edition of the Peer Review Handbook was developed by the U.S. Environmental Protection Agency (hereafter EPA or the Agency) to provide guidance to EPA staff and managers who are planning and conducting peer reviews.

The Agency might want to add additional documents, but these will benefit the peer reviewers with the understanding of the need for quality of scientific information as well as what constitutes "quality" scientific information. In the meantime, how will EPA substantiate its approach as an evaluation of a solid standard scientific assessment per the IAQ guidance on influential information?

[1] *The Perchlorate Information Bureau is supported by Aerojet Rocketdyne, American Pacific Corporation, Lockheed Martin and Orbital-ATK. These companies have worked cooperatively with the U.S. Environmental Protection Agency to increase scientific and medical understanding of perchlorate's risk to human health.*

ED_005043_00062728-00122

Comment 2

As stated in the FRN:

> Submit your comments on the interim list of peer review candidates and draft charge to Versar, Inc., no later than October 21,

And

> Questions concerning the interim list of expert peer review candidates and draft peer review charge questions should be directed to Versar, Inc.

The FRN states that this is an "interim list," but it is unclear the meaning of this term. Is it the intent of EPA or Versar to use the exact same peer reviewers for both peer review panels; will other peer reviewers be evaluated for the second panel; or will a subset be on both panels? Does EPA plan to look for additional experts to fill the subsequent peer review with another FRN?

Comment 3

Versar, Inc. assembled a panel of scientific experts to evaluate the draft BBDR model and draft report. EPA requests:[2]

> ...scientific experts whom [sic] have knowledge and experience in one or more of the following areas: (1) Physiologically-based pharmacokinetic (PBPK), physiologically-based pharmacokinetic/pharmacodynamics (PBPK/PD) and/or Biologically Based Dose-Response (BBDR) modeling, (2) fetal and neonatal thyroid endocrinology (clinical and experimental), (3) iodide homeostasis, and (4) perchlorate toxicology and mode of action or adverse outcome pathway.

This is a limited set of four categories of expertise. On June 3, 2016, EPA sought to expand the expertise since it had combined two peer reviews into one peer review. Because of that, EPA requested additional experts in one or more of the following areas of risk assessment to include:[3]

> An understanding of thyroid function (preferably in the sensitive life stages of interest), the importance of maternal thyroid hormone homeostasis in each stage of gestation, hypothyroxinemia, neurodevelopmental assessment indices for young children including the Bayley's Scale, the toxicity of perchlorate, epidemiological assessment techniques, and statistics.

Clearly the expertise required for the first and second peer reviews are different. A number of the experts in the interim list of 19 peer reviewers appears to fulfill the requirements of the second, but not the first. Will Versar or EPA explain how each of the current group of interim experts fills the categories of expertise requested currently and in March?

Comment 4

The Agency's Peer Review Guidance (2015) states:

> It [Peer Review] is conducted by qualified individuals (or organizations) who are independent of those who performed the work and who are <u>collectively equivalent in technical expertise to those who performed the original work (i.e., peers)</u> [emphasis added].

---

[2] Federal Register (81 FR 10617; March 1, 2016)
[3] Federal Register (81 FR 35760; June 3, 2016)

ED_005043_00062728-00123

> Peer review is an in-depth assessment of the assumptions, calculations, extrapolations, alternate interpretations, methodology, acceptance criteria and conclusions pertaining to the scientific or technical work product, and of the documentation that supports them.

It is unclear what expertise was used to develop the model. If that information were made available, it would assist in obtaining the expertise necessary for this peer review. Additional expertise appears to be missing that would provide key insight to the evaluation of the BBDR model. How does the Agency envision that peer reviewers will assess the assumptions, calculations, extrapolations, *etc.* used by EPA, given the short time for the model review as well as the limitation on expertise? Additionally, to address possible issues of balance and quantity of work to be evaluated at least two, and preferably more, experts would fulfill each category. We suggest the interim list be expanded to include (but not be limited to) the following areas of expertise:

- Computer programming (two different platforms are offered; to evaluate the model codes); particularly experts in AcslX (Aegis Technologies) and R platforms (to provide guidance to experts on questions of software),
- Receptor pharmacology (to provide understanding of basic receptor ligand interactions relating to symporter function),
- Iodine regulation (clinical evaluations as well as iodine homeostasis, biochemistry, physiology, and lifecycle), and
- Statistical assessments (e.g., sensitivity analysis for BBDR models)
- Expert medical PBPK modelers (to compare the Agency's model with best available techniques and practice of modeling).

Comment 5

For this first peer review panel, it is unclear how the BBDR model code evaluation is expected to be conducted. Based on the biographies provided by the contractor, a number of candidates appear to have no experience with BBDR modeling. When they receive the model code, do Versar and EPA expect each panelist to download the model and run it prior to the public meetings? If not, why not? How does the Agency envision obtaining independent scientific advice regarding the model if the panelists cannot or do not run the model? How would EPA evaluate comments of a reviewer who has never run a model compared to a reviewer that has?

Thank you for the opportunity to provide these comments.

Sincerely,

Richard C. Pleus, PhD

RE: Comments on EPA's draft Biologically Based Dose-Response Model and an accompanying draft model report; Docket No. EPA–HQ–OW–2016–0438

Dear Sir or Madam:

We appreciate the opportunity to comment on 1) EPA's draft Biologically Based Dose-Response Model (EPA 2016 Model) and 2) its accompanying draft model report entitled "Biologically Based Dose-Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses" (EPA 2016 Report) posted in the September 30, 2016 Federal Register and in Docket No. EPA-HQ-OW-2016-0438.

The EPA 2016 Model is designed to identify when the infant, breast feeding mother, pregnant mother and fetus have symptoms of hypothyroxinemia (low T4 thyroid hormone) but not symptoms of hypothyroidism (low T4 and elevated Thyroid Stimulating Hormone levels). Hypothyroidism is expected to result from sustained hypothyroxinemia. EPA's Science Advisory Board (SAB) concluded in 2013 that hypothyroxinemia is likely to harm the developing brain of a fetus or infant even if there is no evidence of hypothyroidism.

In essence, the SAB found that hypothyroxinemia is a more sensitive endpoint for fetal brain development than hypothyroidism. When hypothyroidism symptoms are seen, the harm to the fetal or infant brain is likely to be more severe.

For that reason, EPA's statement is particularly significant:

> The model predicts that a pregnant mother and a lactating mother at PND [post-natal day] 60 or 90 who only ingest 75 μg/d of iodine would be hypothyroid even without perchlorate exposure. With an iodine intake of 100 μg/d (considered medically insufficient), both pregnant and lactating mother would be barely within or just below the reference range.[1]

[1] EPA 2016 Report on page 7.

ED_005043_00062728-00126

While conversions between iodine intake and iodine in urine complicates the calculation, we estimate that 20% of pregnant women have iodine intake levels than low enough (< 100 μg/day) to result in hypothyroidism with any exposure to perchlorate.[2]

The statement is even more significant when considering:

- Hypothyroidism is not the most sensitive endpoint. The percentage of pregnant women who cannot tolerate any exposure to perchlorate would be greater if hypothyroxinemia were considered.
- The Food and Drug Administration (FDA) has already demonstrated that most of the food and beverages we consume are contaminated with perchlorate. In 2008, it estimated that women of childbearing age are already exposed to 0.09 to 0.11 μg/day of perchlorate in the diet.[3] This estimate does not consider perchlorate in drinking water.
- The model does not consider the concurrent exposure to nitrates or thiocyanates in the diet. These two other chemicals impair the same iodine uptake mechanism affected by perchlorate. Therefore, the percentage of pregnant women at risk of harm to the fetus would be even greater.

Regarding the EPA 2016 model itself, we think it is a significant improvement over the hypothyroxinemia model proposed by Lumen et al[4] (Lumen 2013 Model) on which it is based and look forward to seeing the results of the external peer review.

However, we have serious concerns that the model does not address the first and second trimesters of pregnancy. Analysis on only the third trimester, when the fetus has a functioning thyroid, falls short of what the SAB recommended. In the first trimester, the fetus has no thyroid and depends on the maternal circulation for an adequate supply of T4, a hormone that is essential to brain development. With two functioning thyroids (the fetus' and the mother's), each with its own reserves of T4 – the situation in the third trimester addressed by the model – appears to be less risky than in the first trimester.

We maintain that in setting an MCLG EPA must consider the impacts on a pregnant women's fetus during the first two trimesters and on pregnant women with serious iodine deficiency and hypothyroidism pursuant to §1412(b)(3)(C)(i)(V) of the Safe Drinking Water Act. The provision states that EPA should consider:

> "The effects of the contaminant on the general population and on groups within the general population such as infants, children, pregnant women, the elderly, individuals

---

[2] The most recent assessment was published by Caldwell KL, Pan Y, Mortensen ME, et al., Iodine status in pregnant women in the United States: national Children's study and national health and nutrition examination survey. Thyroid. 2013;23:927–37. It stated that 26.3 % of pregnant women have urinary iodine concentrations below 100 μg/L, and 15.7% have levels below 50 μg/L. In estimating that 20% of pregnant women, we assumed that urinary iodine levels are 75% of intake.

[4] Lumen A, Mattie DR, Fisher JW. Evaluation of perturbations in serum thyroid hormones during human pregnancy due to dietary iodide and perchlorate exposure using a biologically based dose-response model. Toxicol Sci. 2013 Jun;133(2):320-41.

ED_005043_00062728-00127

with a history of serious illness, or other subpopulations that are identified as likely to be at greater risk of adverse health effects due to exposure to contaminants in drinking water than the general population."

This omission, which the agency states in a follow-up email is due to data limitations, means that the life stages of greatest risk are not modeled. EPA should specifically ask the expert reviewers to consider the implications for the model's relevance. As EPA moves forward with perchlorate drinking water regulations, this shortcoming must be addressed

We discuss these issues in more detail in Attachment A.

In summary, EDF and NRDC believe that EPA's model is a useful step forward in the development of a maximum contaminant level for perchlorate in drinking water. However, it leaves important issues unresolved. The agency must resolve these issues as it completes this step and undertakes the next step in the process.

We appreciate the opportunity to comment, and if you require any additional information, we can be reached at 202-572-3263 or tneltner@edf.org and jsass@nrdc.org.

ED_005043_00062728-00128

Attachment A
Responses to NRDC's Concerns with Lumen Model

In February 28, 2014, the Natural Resources Defense Council (NRDC) identified six recommended improvements to the Lumen et al. 2013 model that was under consideration for a biologically-based, dose-response model (Lumen et al 2013). On March 24, EPA's Eric Burneson, Director of Standards and Risk Management Division, Office of Water, provided feedback from those responses. The recommendations and the responses are described below

1. **Expand the model to include the first two trimesters in addition to infants. The current model is based only on the end of the third trimester when the fetus has a functioning thyroid.**

EPA Response in March 2014: We agree that there is good reason to include at least the first trimester in the modeling because the adverse effects of maternal hypothyroxinemia are thought to be initiated during that period. We are evaluating the existing body of data to see if adequate information is available to consider this sensitive life stage.

EDF & NRDC Comment: According to an October 28, 2016 email to EDF from EPA, the agency did not model hypothyroxinemia the first two trimesters despite agreement that the adverse effects of maternal hypothyroxinemia are thought to be initiated from the first trimester. EPA indicated that there was not adequate information to consider these sensitive life stages for two reasons:

- Free T4 levels in the 1st and 2nd trimester pregnant women were not modeled due to a lack of available published (peer reviewed) data
- Almost no data on the functioning/parameters of the fetal thyroid in those trimesters (after it develops). Apparently, the model for the third trimester uses factors extrapolated from the newborn infant.

We appreciate EPA's prompt response to our request and were surprised that such a critical limitation was not made explicit in the report. Our understanding is that in the first trimester, the fetus does not have a functioning thyroid. So there should be no need to model its production of thyroid hormones. In the absence of reliable data on the 2.5th and 10th percentile of free T4 levels in the first trimester, it seems reasonable to assume that maternal hypothyroxinemia in the first trimester would adversely affect fetal brain development.

In the absence of such critical information, we recommend, at a minimum, that EPA:

- Make the data gap explicit to the external peer reviewers and ask that they comment on EPA's approach to neither model this risk, nor to adjust for it with uncertainty factors.
- The final MCLG should include additional safety factors to protect fetal brain development during the first two trimesters
- EPA should revisit the issue in its six-year review of the standards.

ED_005043_00062728-00129

2. **Ensure the model considers iodide levels at the 95th and 99th percentiles of pregnant women, not just the 90th percentile.**

EPA Response in March 2014: We intend to consider a range of iodide levels as we model perchlorate impacts. We are currently evaluating the literature to determine the range of dietary iodide levels for which thyroxin levels are known. We will consider the impact of extrapolating to low levels of iodide ingestion on model performance if these data are not available.

EDF & NRDC Comment: The model considers only iodine intakes as low as 75 μg/day just as the Lumen et al 2013 model did, and thus EPA's model unfortunately provides no improvements in this regard.

3. **Reevaluate affinity constants for iodide and perchlorate to ensure they are based on a robust data set and are calculated consistently.**

EPA Response in March 2014: We recognize the uncertainty in affinity constants for perchlorate and iodide for the sodium iodide symporter (NIS). We will evaluate the feasibility of conducting a sensitivity analysis to investigate the effect of changes in affinity constants on model outputs.

EDF & NRDC Comment: According to footnote 2 in the report

> "As detailed in this report, the affinity of perchlorate for the sodium-iodide symporter (NIS), a key parameter in the PBPK/BBDR models, was revised based on a re-evaluation of original data. The revised value was substituted into the model of Lumen et al. (2013) in the analyses conducted here." *Footnote 2 of report.*
>
> "Based on re-evaluation of the in vitro data of Kosugi et al. (1996), the affinity constant (Km) for binding of perchlorate to the NIS (KM_TPNG) was reduced from 1.6×10^5 ng/L (McLanahan et al., 2014; Clewell et al., 2007; Merrill et al., 2005) to 6×10^4 ng/L (Schlosser, 2016). This lower value was shown to provide model predictions much more consistent with the radioiodide uptake inhibition data of Greer et al. (2002) for doses up to 100 μg/kg/d than those obtained with the former value for the Km." *Page 45 of report.*

We appreciate EPA's revisions to the Lumen model. They appear to address our concerns.

4. **Incorporate thiocyanate and nitrate in the model as recommended by EPA's Science Advisory Board since they also inhibit iodide uptake in a manner similar to perchlorate.**

EPA Response in March 2014: EPA's current focus is to develop a PBPK model in accordance with the recommendations of the SAB. We recognize that co-exposures to thiocyanate and nitrates (as well as other thyroid hormone disruptors) are likely occurring in the U.S. population. We will strive to address this issue to the extent possible given the current state of the science.

ED_005043_00062728-00130

EDF & NRDC Comment: Nitrates and thiocyanates do not appear to be considered in any way in the model despite evidence that they also interfere with the same symporter affected by perchlorate.

EDF and NRDC maintain that EPA cannot ignore the cumulative effects of nitrates and thiocyanate on the transport of iodine into the thyroid. Pursuant to Section 1412(b)(4) of the Safe Drinking Water Act (SDWA), the Maximum Contaminant Level Goal (MCLG) "shall be set at the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." If nitrates are in drinking water, they will increase the impact of perchlorate. To fulfill its responsibilities under the law, the safe level of perchlorate needs to be adjusted downward to address the contribution of nitrates and thiocyanates.

In addition, SDWA section 1412(b)(3)(C)(i)(VII) would require the agency to consider the impact of nitrates and thiocyanate as another relevant factor. At a minimum, EPA must add a safety factor to account for the presence of nitrates and thiocyanate in the water and the diet.

5. **Justify the selection of 10 pmol/L of maternal free T4 as the threshold for hypothyroxinemia.**

EPA Response in March 2014: Although Lumen et al. (2013) used a target value of 10 pmol/L for free T4, EPA has not yet determined the target levels for hypothyroxinemia for different life stages in the current modeling effort.

EDF and NRDC Comment: Based on our understanding of the model, EPA uses free T4 levels between 2.5th and 10th percentile to define hypothyroxinemia. When free T4 levels fall below the 2.5th percentile, hypothyroidism would be dominant. While hypothyroidism is a less sensitive endpoint, it indicates that there is a sustained reduction in production of T4 and the T4 reserves are too low. Therefore, the risk to fetal and infant brain development is greater.

The EPA 2016 model predicts that a pregnant women would suffer hypothyroxinemia when the free T4 levels are between 10.6 to 11.7 picomolar. In infants, the levels vary with post-natal days. As noted above, there are no estimates for fetuses.

We appreciate EPA's 2016 update of the Lumen et al 2013 model with this more science-based approach. We assume the external peer reviewers that EPA has selected will have an opportunity to evaluate the new model and comment on the merits of EPA's approach.

6. **Compare the model results to NHANES monitoring data**

EPA Response in March 2014: EPA is considering how best to validate the model outputs. We appreciate and will give consideration to your recommendation to compare the model results to the NHANES monitoring data.

ED_005043_00062728-00131

EDF & NRDC Comment: We appreciate EPA's efforts to update its model using the latest NHANES monitoring data.

RE: Comments Submitted by Gradient on Docket No. EPA-HQ-OW-2016-0438: Biologically Based Dose Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses

Dear Mr. Beauvais:

Gradient appreciates this opportunity to submit comments on EPA's draft report concerning the development of a biologically based dose response model for the effect of perchlorate on thyroid hormones on vulnerable populations.[1] Gradient has been involved with human health risk assessment for over 30 years and has extensive experience evaluating physiologically based pharmacokinetic modeling of goitrogens in the context of quantitative risk assessment.

We would like to commend EPA and the report authors for the extensive amount of work done in adapting and expanding on earlier perchlorate modeling efforts. The work summarized in the report is an important advance in the field of biologically-based dose response models, particularly the focus on addressing multiple potentially sensitive subgroups. The ultimate purpose of this work is to create a model that will be used to establish a safe exposure limit for perchlorate. If a model is used for such an application, it is important to clearly describe its assumptions and limitations so that downstream users do not over interpret the model's results. A model used in this way should ideally also be able to describe (even if in general terms) the full extent of goitrogen exposure that the target population will experience. Our specific comments related to these concerns are provided below. We note that many of these comments are consistent with the draft charge questions proposed for the expert panel review.

Comments

Failure to address other goitrogens

1. The EPA modeling report document makes no mention at all of the potential impacts of thiocyanate (SCN) and nitrate (NO_3) on the thyroid and thyroid hormone synthesis. This is not reasonable given that it is known, from multiple scientific studies, that SCN and NO_3 also impact thyroid activity. For example, the Cao *et al.* (2010)[2] study that EPA repeatedly cites in the report found that all three ions were associated with increased urinary TSH in infants exposed to these ions during the first year of life, and that the associations with SCN and NO_3 were observed regardless of iodine status whereas perchlorate's effects were only observed in the low iodine status subgroup (*i.e.*, < 100 μg/day iodine excretion, a situation where the current model is said to be unreliable). Moreover, the multivariate

[1] Gradient is submitting these comments in conjunction with SQM, a manufacturer of fertilizers and other products.
[2] *Environ Health Perspect.* 2010. 118(9): 1332–1337

ED_005043_00062728-00134

model coefficients were larger for SCN and NO_3 compared to perchlorate, indicating they were stronger predictors of TSH.[3] This is consistent with modeling work we haveconducted with the earlier perchlorate model which showed that the NIS inhibiting effects of dietary SCN and NO_3 exposures could dwarf potential exposures to perchlorate.[4] The inability of the current model to address the impacts of these two ions (which are both present at substantial levels in the diet) should, at a minimum, be pointed out as a source of model uncertainty and a need for future research. EPA should consider and discuss how a recent PBPK model of thiocyanate kinetics could be incorporated into the modeling effort (Willemin and Lumen, 2016).[5] The current model's inability to address the impact of other goitrogens (not only those that affect NIS but also others such as soy components) is an important limitation because low level, variable exposures to these chemicals are clearly tolerated in the human population.

2. p. 39. *"The mammary gland is capable of concentrating iodide in breast milk via the sodium iodide symporter (NIS), a membrane bound transport protein that is under the control of prolactin and other hormones (Micali et al., 2014; Semba and Delange, 2001). There are likely several mechanisms involved, including other transporters such as pendrin, but data by which their contribution to iodide transport could be quantified (vs. that of NIS) is lacking. Therefore the model structure only includes NIS-mediated transport between blood plasma and breast milk."*

   Given that the modeling indicates that the lactating woman and the breastfed infant are key sensitive populations, this failure to include other mechanisms of iodine transfer into breast milk is an important area of uncertainty. In Figure 7 (bottom graph, perchlorate), the model predictions appear to approximate the Leung *et al.* (2012)[6] data but, due to the log scale, may in fact inaccurate by several fold. In the corresponding iodide graph (Figure 7, top), the model is clearly over predicting breast milk iodide concentrations. It is unclear why only the Leung *et al.* data are used for comparison. Several other breast milk iodide data sets are available (Kirk *et al.*, 2007; Bruhn and Franke, 1983; Pearce *et al.*, 2007).[7] EPA acknowledges the uncertainty when they later note: *"The range of iodide concentrations in spot breast milk samples can exceed two orders of magnitude, so factors other than variation in dietary intake must influence this range."* The potential impact of other goitrogens is an important concern here.

<u>Failure to address compensation/adaptation</u>

3. The EPA report does not address possible compensation/adaptation in response to decreased T_4 that is insufficient to trigger an increase in TSH above a defined clinical definition value (*i.e.*, hypothyroxinemia *vs* hypothyroidism). Does EPA have any data supporting the idea that no compensation/adaptation occurs until the hormone profile is consistent with hypothyroidism? We could find no data indicating a lack of compensation (alterations in NIS activity, hypertrophy of follicular cells, delayed elimination of T_4, *etc.*) during hypothyroxinemia. This seems to be intuitively problematic given that humans have evolved to respond to slight perturbations in iodide availability as goitrogen intake varies from day to day. A study by Wei *et al.* (2013)[8] reports that a hypothyroxinemia-inducing diet in rats did induce compensatory actions (*e.g.*, increased NIS expression) but unfortunately the authors did not measure TSH so it is unclear whether the rats were truly not hypothyroid. Clearly if some degree of compensation occurs even in hypothyroxinemia, this would need to be addressed in the model. Because the model is entirely premised on the

---

[3] SCN was also a more important predictor of T_4; perchlorate and NO_3 had similar coefficients.

ED_005043_00062728-00135

absence of any compensation during hypothyroxinemia, the impacts of exposure to perchlorate and other goitrogens could be overestimated.

4. p. *16 "In the range of evaluation, it is assumed that there is insufficient feedback control of the T4 concentrations on TSH levels to warrant model description."* Is there insufficient feedback or no feedback? If insufficient, how was this judged? As noted above, this is a critical assumption in the model, *i.e.*, that no compensation or adaptation occurs when an individual becomes hypothyroxinemic. No empirical support is given for this assumption and a more robust defense of this assumption is needed.

<u>The pregnancy model does not address early gestation</u>

5. Multiple studies indicate that the developing fetus is most sensitive to hypothyroxinemia in early gestation and some studies have indicated that hypothyroxinemia in later gestation may not pose risks (Negro *et al.*, 2011).[9] The EPA model (like the earlier model on which it is based) is not a true dynamic model of pregnancy but rather a model of a specific time point late in gestation (*i.e.*, the model considers a woman and a near term fetus but does not include equations describing the growth of the fetus and corresponding maternal changes over the course of pregnancy). How can one reconcile the modeling of only the late stage fetus when studies suggest the early stages of pregnancy are more critical? Furthermore, what does the suggestion that the late stage fetus is relatively more resistant to the effects of maternal hypothyroxinemia than the early stage fetus say about the relative sensitivity of the neonate, in which the thyroid is even more mature? We could find no studies addressing the neurodevelopmental impacts of lactational exposure alone; the sensitivity of the post-natal infant is only inferred from the demonstrated sensitivity to *in utero* exposures (again, typically early in gestation).

<u>Consider the use of probabilistic models</u>

6. EPA should consider using or commenting on the probabilistic version of the perchlorate BBDR model developed by Dr. Annie Lumen (Lumen *et al.*, 2015; 2016).[10,11] This newer code allows for the use of distributions for key model inputs (*e.g.*, maternal perchlorate and iodine dose, drinking water intake) which may provide a more informative prediction for making policy decisions (*i.e.*, in terms of expressing uncertainty *via* a distribution of predicted results). This type of model would also help to better characterize model uncertainties.

<u>Interpretation of Aboul-Khair *et al.* publication on thyroid function during pregnancy</u>

7. p. 38. *"Urinary excretion of iodide was found to decrease over time in 7 lactating women (Aboul-Khair et al., 1964) for postpartum weeks 2, 6 and 12. The urinary iodide excretion clearance values (L/h) and the estimated urinary iodide excretion clearance value from the 3rd trimester mother at birth (Lumen et al., 2013) were used for the lactating mother model for iodide. In a similar trend, the calculated thyroidal uptake of iodide declined over 12 weeks of lactation (Aboul-Khair et al., 1964).*

   A review of the Aboul-Khair study[12] indicates that renal clearance between weeks 6 and 12 post-partum was not significantly different (37.1 ± 2.88 ml/min *vs.* 34.97 ± 2.02 ml/min). Was this time period treated as a constant value in the modeling? Moreover, this very important indicator of maternal iodide kinetics on PND 7 (the day of greatest sensitivity according to the model) is based

---

[9] *Endocr Pract.* 2011. 17(3): 422–9
[10] *Front Pharmacol.* 2015. 6:107
[11] *Toxicol Appl Pharmacol.* 2016. 314:24-38
[12] *Clin Sci.* 1964. 27:195-207

ED_005043_00062728-00136

on an interpolation between PND 0 (based on the Lumen *et al.* model) and PND 14 (based on the Aboul-Khair study). The data supporting this model parameter are very limited and it would be useful to explore this *via* a sensitivity analysis. In addition, the change in iodide uptake by the thyroid in the Aboul-Khair *et al.* study was described by the authors as not significantly different across the post-partum period studied (26.93 ± 2.93, 22.32 ± 2.60, 21.87 ± 2.22 at 2, 6 and 12 weeks, respectively). Why did the EPA apparently address this parameter as declining over time? How does the decision to model a non-statistically significant change as if it were a real difference impact the model predictions?

Need to clarify what is adverse

8. The modeling appears to indicate that the lactating mother (and possibly the pregnant mother) are the most sensitive groups relative to hypothyroxinemia and that the breast fed (and bottle fed) infant are actually less sensitive (*i.e.*, only becoming hypothyroxinemic at higher perchlorate doses, lower iodine intakes) than the mothers (EPA, page 7). The concern about maternal hypothyroxinemia is the effect on the nursing child but the modeling seems to suggest that some level of maternal hypothyroxinemia may not be adverse to the infant (this is implied by the text but never stated). This will complicate the establishment of a thyroid hormone decrement that is considered adverse.

9. p. *17 "Given the lack of a unified clinical definition, for the purpose of this report it is assumed that euthyroid conditions occur for fT4 levels between the 10th and 90th percentile of the entire population in a given life stage, and that hypothyroxinemia occurs for fT4 levels between the 2.5th and 10th percentile for the entire population. When fT4 falls below the 2.5th percentile for the entire population in a life stage, it is assumed that TSH levels would be sufficiently elevated to trigger hormonal feedback, invalidating the model predictions. While model simulation results are shown beyond this range for the purpose of illustration, simulation curves for these results 18 are shown in grey (vs. black) to indicate that the confidence in those model predictions is low (e.g., Figure 10. Free T4 (fT4) levels as a function of perchlorate exposure and dietary iodine ingestion in the gestation-week 40 pregnant mother and fetus."*

   First, we appreciate that EPA is making an effort here to indicate where the model is considered unreliable. While the fT4 population distribution percentages used by EPA to characterize hypothyroxinemia (*i.e.*, 2.5% to 10%) seem to be consensus values, the actual fT4 concentrations (in nM), which are needed to compare to model predictions, seem open to debate (Moleti *et al.*, 2011).[13] Will an agreement on what level of fT4 decrement is adverse be required in order to use the model to establish a reference dose? Would a probabilistic analysis of this cutoff value be helpful?

Need to be transparent on model validation and precision

10. Calibration studies of the model (Figures 4-9) seem to suggest the model is "in the ballpark". That is, when the model is run using a range of iodine intakes (75 to 250 μg/day) the outputs as a whole are in the order of magnitude range of the results reported in epidemiology studies. This suggests the model is accurate but is not very precise. That is, the model may not be able to reliably distinguish a safe level of exposure of for example, 4 μg/kg-day vs 12 μg/kg-day.[14] EPA should be very clear about the model's predictive precision. All too often, policy makers impute much more precision to models than they actually deserve.

11. EPA should consider conducting a multivariate sensitivity analysis. An extremely large number of model parameters are either fit values or referenced to prior modeling efforts (where they were also

---

[13] *J Thyroid Res.* 2011. 463029

[14] These values are used to illustrate the comment but do not represent actual model generated values or measured precision of the model.

ED_005043_00062728-00137

fit values). Thus many of the key inputs are not based on study data for that particular value but were chosen because they seem to work in the model. While this is not unusual, multiple combinations of different input values could equally lead to the same results.

12. p. 17, *"The actual range of model accuracy is uncertain, due to the fact that the data on urinary and breast milk iodide levels, and TH blood levels, are generally not correlated with specific iodine intake levels (doses). Hence model predictions of fT4 as a function of iodine dose cannot be evaluated or calibrated against corresponding dose-response data."* It would be helpful to acknowledge this uncertainty in the executive summary.

13. p. 18 *"the model predictions are likewise judged to be reliable for ≥ 150 μg/d iodine, but to have increasing uncertainty at 100 μg/d iodine (where maternal fT4 approaches the bottom of the reference range)"* Does this mean that the model should only be used to set acceptable perchlorate intakes where the iodine intake is 150 μg/d or higher? This would have an important impact on the use of the model.

Do the model predictions match existing data?

14. p. 8. *"The model predicts that a pregnant mother and a lactating mother at PND 60 or 90 who only ingest 75 μg/d of iodine would be hypothyroid with no perchlorate exposure."* A review of the available epidemiology data indicates this prediction is neither supported nor contradicted by the data. There are surprisingly few studies examining the correlation between urinary iodine concentrations and thyroid parameters and even fewer that find an effect of iodine insufficiency on such parameters among pregnant and lactating women. We note a recent study by Liu *et al.*[15] reported that even in an iodide deficient population of lactating women (75th-tile urinary iodide = 73.65 μg/l), only a small percentage (3.77%) of subjects were hypothyroid and only 17% were said to be hypothyroxinemic. EPA should include a discussion of how well the model prediction is matched by actual data as a matter of transparency. More broadly, this is a very complex model with many inputs and predictions. It would be helpful to include a table of model predictions (*i.e.*, maternal urinary iodide, breast milk perchlorate, *etc.*), the data sets to which they are compared, and a general statement of the degree of precision and accuracy.

EPA modified the NIS inhibition parameters of perchlorate to better fit experimental data

15. p. 45. The report describes how EPA changed the Michaelis-Menten values for NIS inhibition by perchlorate based on a re-analysis of Kosugi *et al.* (1996) (described in more detail in the appendices).[16] Although not directly addressed in the report, it appears that EPA has effectively doubled the potency of perchlorate as an inhibitor of NIS iodide uptake relative to what was reported by Tonacherra *et al.* (2004).[17] The results of Tonacherra *et al.* are also consistent with what can be obtained from Greer *et al.* (1966), Wyngaarden *et al.*, (1953) and Alexander and Wolff (1966).[18] While it is reasonable to reanalyze older data using more sophisticated methods, if EPA's assessment of perchlorate's NIS inhibiting potency is inconsistent with multiple prior studies, this needs to be explained. As a matter of transparency, the relative potency of iodide, perchlorate, SCN and NO_3 is familiar and well understood to the broader audience. It would be helpful for EPA to incorporate this concept into the discussion.

ED_005043_00062728-00138

More explanation is required on why the BBDR model does not address the first few days of life

16. p. 21. *"Changes in TH kinetics have been noted in the first few days after birth (Fisher and Klein, 1981; Jacobsen et al., 1977; Erenberg et al., 1974; Abuid et al., 1973)."* The modeling as described in the report only focuses on PND 7. Did EPA attempt to model earlier time points? Were there no data to support assumptions?

Points concerning clarity of the text or need for additional discussion

17. p. 7. In the summary on page 7, why does EPA focus on perchlorate exposures below 20 μg/kg-day when the existing RfD is 0.7 μg/kg-day? The wording used is vague: "the lactating mothers were predicted to become hypothyroxinemic or hypothyroid at perchlorate exposures below 20 μg/kg/d, even with daily iodine intakes of 250 μg/d." Why not indicate the exposure level where hypothyroxinemia did not occur, which is the value of ultimate interest?

18. p. 7. *"the lactating mothers were predicted to become hypothyroxinemic or hypothyroid at perchlorate exposures below 20 μg/kg-day."* EPA is been very clear that the model is not reliable in the range associated with a hypothyroid condition, therefore the prediction cannot distinguish between hypothyroxinemia and hypothyroidism.

19. p. 11. "*Thus adverse effects of moderate postnatal thyroid hormone decrements (hypothyroxinemia) on neurodevelopment in full term (born healthy), nursing or bottle-fed infants have not been studied. However, as described in a detailed review by U.S. EPA (2012), a reduction in the storage of thyroid hormone and iodine, as well as rapid thyroid hormone turnover (i.e., shorter half-life) in the fetus, neonates and children makes these life stages more sensitive to thyroid disrupting agents such as perchlorate compared to adults. Furthermore, the physiological demand for thyroid hormones is far greater in the developing fetus, neonate and child compared to the adult, again increasing the vulnerability to thyroid disrupting agents."*

    EPA acknowledges that the key efects they are concerned with have not been demonstrated in the literature (as concerns neonatal exposure). EPA then cites their own prior logical argument as support for this concern. This seems rather weak support for such a critical aspect of the work.

20. p. 12. EPA states that Fisher *et al.* (2016)[19] and SAB (2013)[20] provide strong support that the infant is particularly sensitive to perchlorate exposure. The Fisher *et al.* paper describes an earlier version of the same model EPA is discussing. So essentially the argument is that the current model needs to be concerned about infants because the model shows infants to be susceptible. That is rather circular. The Fisher *et al.* paper only discusses perchlorate in the context of it having been a focus of earlier models. Furthermore, although the Science Advisory Board did direct EPA to consider infants as a vulnerable population group, they also noted: "Although adverse neurodevelopmental effects of perchlorate in infants and children have not been reported in the literature, the risk of adverse effects can be reasonably inferred from perchlorate's mode of action and the known role of thyroid hormone on human brain development." (p.2) We agree that the SAB's reasonable inference is valid but are skeptical that an inference where study data are lacking can be called *strong* support.

---

[19] *PLoS One*.2016 11(3):e014930

[20] "SAB Advice on Approaches to Derive a Maximum Contaminant Level Goal for Perchlorate." EPA-SAB-13-004

21. p. 13 (bottom of page). EPA states that the lactating mother and neonate are the most sensitive subpopulations but earlier stated that it is not clear whether the pregnant woman or lactating woman are more sensitive. The discussion should be consistent.

22. Figure 2 is a bit confusing with the volume of distribution (Vd) shown separate from the biological compartments (with which it is synonymous). EPA might consider an explanation as to why Vd is shown separately.

We request that EPA and the expert panel consider the points noted above in finalizing the model, which will be a critical tool for setting safe exposure levels. We appreciate the opportunity to provide this input.

Sincerely,

Subject: Request for Public Comments To Be Sent to EPA on Peer Review Materials To Inform the Safe Drinking Water Act Decision Making on Perchlorate [81 FR 67350, September 30, 2016]

NASA thanks EPA for the opportunity to provide comments, issues, and requests during the public comment period for the proposed Perchlorate model. NASA reviewed the proposed model and identified procedural, as well as, general and specific technical issues summarized below. These comments are intended to target gaps and approaches, which if addressed, will improve the efficacy and applicability of the model used in the development of an MCL for Perchlorate. NASA supports sound science as a foundation for regulatory action and appreciates EPA's consideration of this and all other input during the public comment period.

NASA requests EPA address specific procedural issues that impacted on the ready identification of scientific and technical issues during this review process. Independent, rigorous peer review provides the best method to consider and address emerging scientific or technical disagreements. EPA's decision to separate the draft peer review charge questions from the public comment review of the model hampered the reviewer's ability to link issues with the model with the crucial direction provided to the peer review process. The peer review charge questions were subjected to a shorter comment period with EPA providing little clear direction on how specific critical issues identified in the actual review of the proposed model, in subsequent public comment, would be considered during peer review.

In addition, EPA stated that its contractor, Versar, would summarize the public comments that would be shared with the peer reviewers. Such an approach limits the peer reviewers' ability to see the depth and range of public comments for consideration This practice is contrary to the open and complimentary provision of all public comments for reviewers. Independent, rigorous peer review provides the best method to consider and address emerging scientific or technical disagreements. Versar would also summarize the peer reviewers' comments and draft the final peer review report. Generally, an independent peer review report is drafted by the participating members. EPA's approach with the lack of clear direction, support for open sharing of information and the peer reviewers' control over their deliberations presents a troubling approach that threatens to cripple the independent and informed nature of peer review for the proposed Perchlorate model. Also EPA has not indicated how the proposed peer review of the model would be considered. EPA is silent on whether the peer review serves as a majority report, delineating next steps or simply a collection of opinions (often referred to as a letter report) for EPA to consider. NASA again stresses the value of a rigorous, independent peer review to address outstanding scientific and technical issues in the development of sound policy and

regulatory actions. We request EPA provide clear direction and transparency for a robust and effective peer review of the proposed Perchlorate model.

NASA also submits comments on scientific and technical issues identified in the review of the proposed Perchlorate model. This review serves to raise major issues to EPA with the request for response or the incorporation of outstanding issues into the peer review process for appropriate resolution.

Primarily, NASA notes the significant contributions and technical expertise for PBPK modeling of Perchlorate provided to EPA by Food and Drug Administration (FDA) and Department of Defense (DoD) scientists and researchers. We strongly suggest EPA give focused consideration to the technical issues raised by these experts in the FDA and DoD public comments. In a unique partnering effort, EPA collaborated heavily with these experts in various phases of the development of the proposed model. In support of the previous interagency collaboration, NASA concurs with DoD and FDA on the scientific and technical issues identified during this public comment period. We request EPA address outstanding gaps, issues, or need for clarification or validation contained in the expert input found in FDA and DoD comments.

NASA identifies additional areas of concern. The first major issue is EPA's fundamental assumption of using hypothyroxinemia as the end point. NASA understands that the SAB took this very conservative approach to target a specific condition not directly associated with a health impact. However, EPA's use of this endpoint in the proposed model lacks any substantiation in the available literature, especially for critical criteria, such as the Mode of Action (MOA), links to a disease state, or key thyroid endpoints. Additional questions arise over the relationship between EPA's estimation of Perchlorate exposure and the likely relevant Perchlorate exposures. EPA is strongly encouraged to request peer review and suggested approaches to strengthen the proposed model, based on expert opinion and alternative literature-supported approaches, especially in the consideration of the roles of TSH, T3, fT4 hormones on the impacts on the thyroid in the presence of Perchlorate. The proposed model serves as the basis for far-reaching regulation and would greatly benefit from rigorous, scientific reflection of the peer-reviewed literature.

Second, NASA's review identified the need for formal calibration of the proposed model, crucial steps to ensure scientific integrity. EPA notes that the proposed model is calibrated (refer to Pages 27-29 and 60-68) but lacks documentation to support this fundamental step. EPA needs to provide this documentation to the peer review panel for consideration and should make this determination public in the peer review report.

Third, an independent evaluation and validation of the model is critical to truly understanding the strengths, weaknesses and opportunities to improve the model in application. Questions over the proposed model's ability to track with results in existing literature further fuel the need for an independent validation. Currently EPA does not expressly request, via the proposed charge questions, that the peer reviewers conduct model validation but should expand the peer review charge questions to explicitly ensure model validation with substantiating documentation.

Fourth, EPA incorporated numerous assumptions and alternative approaches throughout the proposed model. Among these assumptions are contentious issues, such as its consideration of sensitivity, lack of application to the developing fetus (EPA's decision to not target this potential sensitive subpopulation runs contrary to the SAB direction), assumptions on the nature and impacts of Perchlorate exposure in specific subpopulations, and rates of urinary clearance. EPA does not adequately support these assumptions, further complicating the review by providing contrary uses of existing data, such as from the Greer study (the basis of the National Academy of Sciences report, "Health Implications of Perchlorate Ingestion, 2005). NASA strongly suggests EPA use an open, rigorous peer review of the proposed model to consider and advise on the nature and application of these and other critical assumptions in the formulation of the model.

Again, NASA thanks EPA for the opportunity to review and comment on the proposed Perchlorate model. We strongly request that EPA consider and address the procedural and technical issues identified, especially the strengthening of the rigor and independence of the peer review process, the detailed technical issues raised by partnering DoD and FDA scientists, clarification of the outstanding assumptions and lack of model calibration and validation. We all support sound science in decision making and see these approaches as integral to the formulation of a defensible and applicable Perchlorate model.

RE: Request of the Perchlorate Study Group for an Extension of the Public Comment Period on the "Material to Inform the Safe Drinking Water Act Decision Making on Perchlorate" Docket No. EPA-HQ-OW-2016-0438 [81 Fed. Reg. 67350 (September 30, 2016)]

Dear Assistant Administrator Beauvais:

The Perchlorate Study Group (PSG) hereby requests that EPA extend the public comment period on the draft *Biologically Based Dose-Response (BBDR) Model for Perchlorate* and the accompanying draft model report entitled *Biologically Based Dose-Response Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Modal Development, Revision, and Preliminary Dose-Response Analyses* for 45 days until December 29, 2016.

A 90-day comment period is the minimum necessary to allow stakeholders an adequate opportunity to understand, evaluate and prepare comments on these materials for the following reasons:

- In 2005 the National Academy of Science recommended that EPA develop a PBPK model for perchlorate in drinking water. EPA elected to not do so until its Science Advisory Board made the same recommendation in 2013. It has taken EPA more than three years since that time to develop the proposed BBDR model. Now, after more than 11 years, EPA is proposing to limit unnecessarily the public's opportunity to analyze and comment on the model. Limiting the comment period to 45 days does not allow for the type of meaningful input from the public that is the essence of notice and comment rulemaking. Providing another 45 days for that review is not unreasonable or unwarranted.

- The Safe Drinking Water Act requires EPA to use the "best available science" when setting a maximum contaminant level. A thorough, objective and unbiased review of the proposed BBDR model by stakeholders is essential to ensuring that the agency has indeed employed the best available science. Such a review cannot be legitimately conducted in 45 days.

- To fully understand and evaluate the extraordinarily complex BBDR model, it is necessary to "deconstruct" it, including identifying and evaluating all of the scientific and policy assumptions embedded in the model. The EPA Perchlorate SAB panel recognized PBPK/PD modeling as "an important and novel opportunity that should be implemented carefully with attention to data quality and methodological rigor." [EPA Perchlorate SAB Report (2013), pp. 3-4.] The SAB panel, clearly acknowledging the complexity of the model and the difficulty to be faced by the public in understanding the model, recommended EPA "develop a clear communications strategy ... [that] will facilitate stakeholder and public understanding of ..." of EPA's approach. (Id. at 19). The SAB panel went on to "emphasize the need for ... transparency and robust explanation of [EPA's] approach and modeling ..." (Id at. 26.) EPA's proposed 45 day comment period does not provide stakeholders with a reasonable opportunity to identify and test the validity of the assumptions EPA has made nor to evaluate whether the model legitimately can predict the effects of perchlorate on human health. As such, it is inconsistent with the SAB recommendations.

- EPA released the model code on two software platforms: AcslV, and "R." The software platform on which BBDR model was developed - AcslV - has been discontinued by the manufacturer and is not available for download. "R" is a free software environment, but several "add-ins" are necessary for a BBDR model to operate on this platform. These add-ins are variations on "R" and require sufficient time and learning to incorporate and develop a working knowledge. EPA's decision to develop the BBDR model on a discontinued software platform is ample reason by itself to extend the public comment period.

The PSG appreciates EPA's willingness to maintain a constructive dialogue with us during the many years that it has been evaluating whether to establish a SDWA standard for perchlorate. We simply ask that the agency be consistent and allow for a reasonable time period for a thorough consideration of the BBDR model.

Thank you.

Sincerely,

Tom Roberts

Hi Eric,

We received the final Peer Review report on Friday. See attached.

Once I get clearance from Lisa I will post to the Docket. We have also drafted an update to the perchlorate website to announce the availability of the report. We also intend to simultaneously send an email blast to the EPA working group as well as to all the attendees to the public meeting announcing the availability.

Let me know if you have any questions or comments.

Thanks
Sam

Hi,

I'm sorry, I just realized the earlier message I sent to all of you had an incorrect version of the FRN document.

Please find the correct version attached to this email. My apologies.

Thanks
Sam

Subject: Draft Perchlorate FRN
Attachments: Version-Control Perchlorate Rule FRN 11-21-18 SHQ.docx

Hi,

Attached you will find the draft Preamble and Regulatory text for the Proposed Perchlorate Rulemaking effort.

Please send your comments and/or edits to me and I will incorporate in the controlled version of the document.

Thank You
Sam

I. BACKGROUND

Introduction

EPA is developing approaches to inform the derivation of a Maximum Contaminant Level Goal (MCLG) for perchlorate. In January 2017, EPA's contractor (Versar, Inc.) conducted an independent, external, scientific peer review of the draft biologically-based dose-response (BBDR; also known as a PBPK/PD) model and report titled *BBDR Models for the Effect of Perchlorate on Thyroid Hormones in the Infant, Breast Feeding Mother, Pregnant Mother, and Fetus: Model Development, Revision, and Preliminary Dose-Response Analyses*. The model predicts the relationship between perchlorate exposure and thyroid hormone levels in sensitive life stages and has been revised based on peer reviewer recommendations.

The purpose of this review is to seek guidance from expert peer review on the scientific assessment titled *Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water* (e.g., MCLG Approaches Report) that links the revised perchlorate BBDR model predictions to neurodevelopmental effects to inform decision-making for perchlorate under the Safe Drinking Water Act. The outcome of this peer review is not the derivation of an MCLG; rather, it is to solicit expert comment on the proposed approaches that might be used to inform future decisions on the derivation of an MCLG.

MCLGs are non-enforceable, health-based goals that EPA sets for each regulated drinking water contaminant. In accordance with the Safe Drinking Water Act (SDWA), they are set at a level at which no known or anticipated adverse human health effect occurs and to allow for an adequate margin of safety. MCLGs consider only public health, and not limits of analytical measurement and treatment technology effectiveness. SDWA requires that EPA establish the enforceable Maximum Contaminant Level (MCL) as close as feasible to the MCLG taking costs and benefits into consideration.

Peer Review History

In 2012, as a part of the National Primary Drinking Water Regulation development process for perchlorate and in accordance with the requirements of the SDWA, EPA sought recommendations from EPA's Science Advisory Board (SAB) on approaches to inform the derivation of a perchlorate MCLG.

In 2013, the SAB recommended the following:

- derive a perchlorate MCLG that addresses sensitive life stages through physiologically-based pharmacokinetic/pharmacodynamic modeling (PBPK);
- expand the modeling approach to account for thyroid hormone perturbations and potential adverse neurodevelopmental outcomes from perchlorate exposure;
- utilize a mode of action framework for developing the MCLG that links the steps in the proposed mechanism leading from perchlorate exposure through iodide uptake inhibition to thyroid hormone changes and finally neurodevelopmental impacts; and
- extend the [BBDR] model expeditiously to…provide a key tool for linking early events with subsequent events as reported in the scientific and clinical literature on iodide deficiency, changes in thyroid hormone levels, and their relationship to neurodevelopmental outcomes during sensitive early life stages.

ED_005043_00063236-00003

The SAB stated that this data-driven approach represents a more rigorous way to address differences in biology and exposure between adults and sensitive life stages than is possible with the default approach for deriving an MCLG, and that EPA should also consider available data on potential adverse health effects (neurodevelopmental outcomes) due to thyroid hormone level perturbations regardless of the cause of those perturbations. See Advice on Approaches to Derive a Maximum Contaminant Level Goal for Perchlorate, EPA-SAB-13-004.

Based on the SAB's recommendations, EPA, with contributions from the Food and Drug Administration, developed a BBDR model to predict the effect of perchlorate on the thyroid gland in formula-fed and breast-fed infants, and in lactating women. This draft model was integrated with a previously published model that similarly predicted the effects of perchlorate on serum thyroid hormone concentrations in the 3rd trimester pregnant woman and her fetus. The model was subjected to external peer review in January 2017. The final peer review report titled *External Peer Review for EPA's Draft Biologically Based Dose-Response (BBDR) Model and Draft BBDR Model Report for Perchlorate in Drinking Water* is available through the docket at https://www.regulations.gov/docket?D=EPA-HQ-OW-2016-0439

Revisions to the BBDR Model Following January 2017 Peer Review

EPA considered all of the peer reviewers' recommendations from the January 2017 peer review and focused on those that were anticipated to be most important for increasing the scientific rigor of the model and modeling results. These revisions are summarized in Chapter 3 of the MCLG Approaches Report; additional detail is available in Appendix E. Model revisions focused on the following key recommendations:

- extending the model to early pregnancy;
- incorporating biological feedback control of hormone production via TSH signaling, such that the model can describe lower levels of iodide nutrition;
- calibrating the model and evaluating its behavior for upper and lower percentiles of the population, as well as the population median; and
- conducting an uncertainty analysis for key parameters.

The revised BBDR model does not explicitly address consideration of other goitrogens. Previous peer reviewers (2017) were mixed on their recommendations regarding the issue of consideration of other goitrogens. A recent review of thiocyanate pharmacokinetics and modes of action indicates that an attempt to address other goitrogens in the model would involve significant uncertainty (Willemin & Lumen, 2017). However, it is expected that the model predictions may, in fact, incorporate the effect of perchlorate along with exposure to other goitrogens because the model predictions for zero perchlorate exposure are calibrated to National Health and Nutrition Examination Survey (NHANES) data, which are from a population with an exposure distribution to other goitrogens that is assumed to be independent of perchlorate.

EPA's Approaches for Informing the Derivation of an MCLG

EPA has developed a two-stage approach linking the revised BBDR model results with quantitative information on neurodevelopmental outcomes from epidemiological studies. EPA has also developed an alternative population-based approach that uses the revised BBDR model to evaluate a shift in the population of pregnant women who could be hypothyroxinemic.

ED_005043_00063236-00004

The first stage of the two-stage approach is the development of the revised BBDR model that describes thyroidal hormone production in women of childbearing age with low/adequate iodide intake and predicts the relationship between perchlorate exposure and changes in thyroid hormone levels in early pregnancy. The available data for the second stage of the analysis comes from epidemiological studies that evaluated maternal thyroid hormone levels in early pregnancy and neurodevelopmental outcomes (these are not studies evaluating perchlorate exposure). Based on the recommendations of previous peer review panels, EPA assumed that changes in thyroid hormone levels would be expected to lead to neurodevelopmental outcomes. For this reason, EPA did not conduct a complete, systematic review of the body of literature on this topic. However, EPA conducted a focused review of the published literature and identified 29 epidemiological studies that examined thyroid hormone levels and neurodevelopmental outcomes. Of these 29 studies, fourteen provide categorical data that assist in understanding the implications of altered thyroid hormones, and fifteen provide more detailed dose-response characterizations via regression analyses to inform the relationship between low thyroid hormone levels and neurodevelopmental effects in offspring.

EPA focused on the latter set of fifteen studies due to their more robust dose-response analyses, which included studies that found statistically significant changes and studies that did not find a statistically significant correlation. Among these studies, the number of subjects ranged from 22 to 3,839. In many of these studies the general outcomes, though not statistically significant showed a positive relationship that was consistent with the studies used for quantitative analyses. In some instances, the studies had results that were negative or inconsistent with the studies that were used for the quantitative analyses. EPA presents and characterizes all of these studies in Chapter 5 of the report.

Five studies in this group of fifteen were identified (Pop et al., 1999; 2003; Finken et al., 2013; Korevaar et al., 2016; and Vermiglio et al., 2004) that included data that were used to quantitatively describe the relationship between thyroid hormone levels in early pregnancy (the focus of the analysis) and changes in neurodevelopment in offspring. Neurodevelopmental outcomes associated with these studies included assessment of Bayley Scales of Infant Development, Weschler Intelligence Scales for Children, a Dutch non-verbal intelligence test (the Snijders-Oomen Niet-Verbale Intelligentie Test) and Standard Deviation of Reaction Time

Using the output from the revised BBDR model (stage 1 of the analysis) and the quantitative relationships between thyroid hormone levels and neurodevelopmental effects from the published epidemiological studies (stage 2 of the analysis), EPA characterized the relationship between perchlorate exposure on fT4 levels in pregnant mothers during early gestation and the potential for changes in neurodevelopmental outcomes in their offspring.

EPA's alternative population-based approach estimates the shift in the population of hypothyroxinemic, pregnant women that would result from perchlorate exposure. EPA used the BBDR model predictions to estimate the proportion of hypothyroxinemic pregnant mothers in the population, assuming a distribution of fT4 levels with a consistent iodide intake.The U.S. EPA's Office of Water is in the process of developing National Primary Drinking Water Regulations for perchlorate under the Safe Drinking Water Act. In 2012, EPA submitted a white paper *Life Stage Considerations and Interpretation of Recent Epidemiological Evidence to Develop a Maximum Contaminant Level Goal for Perchlorate* (U.S. EPA, 2012) to the Science

ED_005043_00063236-00005

Advisory Board (SAB) for review. The white paper presented scientific information published since the National Research Council (NRC) released their 2005 Report "Health Implications of Perchlorate Ingestion" and described how EPA derived a range of Maximum Contaminant Level Goal (MCLG) values for life stages of concern. In their 2013 report, the SAB concluded that EPA should: 1) consider exposure to the following sensitive life stages: the fetuses of hypothyroxinemic pregnant women and infants exposed to perchlorate through either water-based formula or the breast milk of lactating women, and 2) derive the MCLG using a physiologically-based pharmacokinetic/pharmacodynamic (PBPK/PD) model to account for exposure differences and biological differences across life stages, including sensitive life stages. Specifically, the SAB found that the 'default algebraic approach provides limited ability to address the various exposure and biological factors affecting sensitivity to perchlorate at different life stages.' The SAB concluded that from a scientific standpoint it would be more appropriate to base the MCLG derivation on the perchlorate mode of action, using PBPK/PD modeling to relate perchlorate concentrations in drinking water to biological effects rather than the default approach.

The SAB report referenced a report by Lumen et al. (2013) on the effect of perchlorate on thyroid hormone perturbations for pregnant mothers and fetuses, as well as their work to extend a physiologically-based pharmacokinetic/pharmacodynamic iodine uptake inhibition (PBPK/PD-IUI) model with links to serum thyroid hormone levels, as a starting point for EPA's efforts.

The new modeling effort presented here integrates the previous EPA PBPK model (2009) for perchlorate with the model developed by Lumen et al. (2013) for pregnant mothers and fetuses (humans) and iodide models developed by Fisher et al. (2013) for lactating rats and Fisher et al. (2016) for lactating mothers and nursing infants (humans). The model has been subjected to a quality assurance (QA) review that was conducted by Oak Ridge National Laboratory (data and parameters used) and Pacific Northwest National Laboratory (model code). The Biologically Based Dose Response (BBDR) model predicts thyroid hormone perturbations for lactating mothers, breast-fed infants and bottle-fed infants resulting from exposure to perchlorate under different dietary iodine intake levels. EPA is relying on the Lumen et al. (2013) model, peer reviewed and published previously, to predict effects for pregnant mothers and fetuses. It is important to note a modification to a key parameter was made (Michaelis-Menten constant for the sodium-iodide symporter for perchlorate, Km) and the thyroid hormone predictions were adjusted for pregnant mothers and fetuses in the model report under review.

EPA is seeking comments on the scientific rigor of the model for evaluating the effects of perchlorate on thyroid hormones in lactating mothers, breast-fed infants and bottle-fed infants under different iodine intake levels. EPA is providing access to the model program code and all necessary files to facilitate use of the BBDR model by peer reviewers and the public. EPA expects that those reviewers with the appropriate software and expertise will be able to replicate the results described in the BBDR model report. After completing development of the BBDR model in the acslX software, the U.S. EPA created a copy of the model that can be run in the alternate software, R. The report URL with links to the code (acslX and R versions for both the pregnancy and infant/lactation models) is:
https://hero.epa.gov/hero/index.cfm/reference/details/reference_id/3352518

ED_005043_00063236-00006

Note that the model is calibrated and expected to be valid for conditions where feedback regulation due to variations in thyroid-stimulating hormone (TSH) levels is minimal, so all charge questions regarding the model are for that range.

In March 2016, the Agency invited the public to nominate scientific experts to be considered as panelists for peer review of the draft model and accompanying report. In June, EPA announced that to achieve efficiency it was expanding the scope of the peer review to include draft approaches for application of the model to inform the development of a perchlorate MCLG. EPA has since reevaluated the review process in response to concerns that a simultaneous review of approaches for application of the model to develop a perchlorate MCLG would not allow for prior consideration of peer reviewer comments specifically on the model.

Therefore, EPA seeks public comment and peer review on the modeling approaches and the ability of the model to predict outcomes that could potentially be used to inform the derivation of an MCLG. EPA intends to seek input on the application of the model for developing approaches for a perchlorate MCLG determination at a later date. Future efforts will include discussion of health endpoints and response levels that are most appropriate to base the MCLG determination.

DRAFT

ED_005043_00063236-00007

II. CHARGE TO REVIEWERS

Topic #1: General Questions

1. Please comment on the appropriateness of focusing the current evaluation on perchlorate's potential impact on the fetuses of hypothyroxinemic pregnant women during early gestation for the purposes of informing a perchlorate MCLG.

2. Please identify any additional peer-reviewed studies that could inform the BBDR modeling or the quantitative relationship of thyroid hormone levels to neurodevelopmental outcomes. If an alternative study data set would be more appropriate, please outline how such data might be used.

Topic #2: BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy

The revised BBDR model seeks to predict the pharmacokinetics and pharmacodynamics of iodide and perchlorate, as well as the thyroid hormones T3 and T4 and TSH, in non-pregnant and pregnant women, including those with low iodide intake, and changes in thyroid hormone levels.

3. Please comment on the assumptions, strengths and limitations of methods and parameters by trimester for:

    a. determining the quantitative relationships between oral intake and serum levels of perchlorate during pregnancy under continuous exposure assumptions, and

    b. estimating statistical distributions of specific biochemical parameters that determine serum perchlorate concentrations, urine clearance of iodide and perchlorate, and thyroid iodide uptake for purposes of estimating the effect of environmental levels of perchlorate on maternal fT4 concentrations.

4. Please comment on the assumptions, strengths and limitations of the uncertainty analyses of the parameters, particularly with regard to availability of data supporting parameter assumptions.

5. Please comment on the utility of the BBDR model for predicting variability in fT4 levels in the population (e.g., percentiles for different thyroid hormone levels) at varying levels of iodide intake.

6. Please comment on the robustness, precision and sensitivity of the model, and how these factors affect the model's ability to predict changes in fT4 at low perchlorate doses. Consider whether a perchlorate dose range exists for which the modeling predictions would be highly uncertain.

7. The revised BBDR model incorporates a TSH feedback loop defined by an equation from Hadlow et al. (2013) (J Clin Endocrinol Metab, 98(7): 2936-2943), with an adjustment factor

ED_005043_00063236-00008

to match specific data sets or population percentiles, to describe the relationship between fT4 and TSH.

a. Please comment on the assumptions, strengths and limitations of this approach to incorporate a TSH feedback loop into the BBDR model.

b. Noting the reliance on the Hadlow et al. (2013) study, please comment on whether there are other studies that should be considered and describe how they would improve the analysis.

c. Please comment on the approach for characterizing inter-individual variability in relevant populations from which the epidemiological data were obtained.

8. Since the observational thyroid hormone data that are used to calibrate the model derive from populations exposed to goitrogens other than perchlorate, EPA has made an assumption that the model parameters may implicitly account for exposures to these other goitrogens. As such, the exposure to perchlorate is assumed to be effectively added to this background goitrogen exposure as discussed in Chapter 3.5 of the report.

   a. Please comment on the validity of this assumption and the extent of uncertainty associated with this assumption.

Topic #3: Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes

9. EPA conducted a three-step literature review, which identified 15 studies with information that could inform the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes.

   a. Please comment on whether EPA has clearly identified the criteria to identify studies through each of the three steps of the literature review, and the adequacy of the strategy for conducting the literature search. Are these criteria scientifically supportable, and did EPA apply them properly?

   b. Please also comment on the summary and characterization of the literature in Chapter 5 of the MCLG Approaches Report and identify any inaccuracies or mischaracterization of the studies.

10. EPA focused on five studies that evaluated the relationship of maternal fT4 and several neurodevelopmental endpoints (IQ, MDI, PDI and reaction time) based on the measurement of fT4 during early pregnancy at weeks 12, 13 and 16.

    a. Please comment on the assumptions, strengths and limitations of focusing on the five studies and associated neurodevelopmental end points to inform an MCLG, including but not limited to study design, evaluation of neurological endpoints, sample size, iodide nutrition status, potential confounders such as smoking, and study population.

ED_005043_00063236-00009

b. Please comment on whether the chosen studies are sufficient in number, quality, and robustness for the purpose of informing the derivation of an MCLG.

c. Please provide advice on reducing any identified limitations.

11. EPA used regression analyses to predict the magnitude of change in each of the neurodevelopmental endpoints given a change in fT4 as a result of increased perchlorate exposure at different iodide intakes.

    a. Please comment on the assumptions, strengths, and limitations of using the regression analyses to inform the relationship between thyroid hormone levels and neurodevelopmental outcomes. Please also comment on the various functional forms of the regression equations (e.g. linear, log-linear, quadratic) in each of the relationships.

    b. Please identify additional data or analyses EPA could use to quantify the relationship between thyroid hormone levels and neurodevelopmental effects, including how this information would be expected to improve the analysis.

    c. Please comment on whether there is a magnitude of change in fT4 below which the relationship between fT4 and neurodevelopmental effects should not be used because it is too uncertain.

    d. Please comment on whether other studies that were identified in the literature search (e.g., studies that found categorical relationships between fT4 and neurodevelopmental outcomes, studies that found effects but lacked statistical significance, studies that did not find an effect) could be utilized to quantitatively characterize the relationship between fT4 and neurodevelopmental outcomes or inform uncertainty associated with the analysis presented.

Topic #4: Alternative Population-Based Approach and Comparison to the Two-Stage Approach Linking Thyroid Hormone Levels to Neurodevelopmental Outcomes

12. Please comment on the assumptions, strengths and limitations associated with the population-based approach that is focused on a shift in the proportion of the population that could be considered hypothyroxinemic.

13. Hypothyroxinemia is the condition of having an abnormally low level of T4 in the blood and TSH is in the normal range, and in diagnosing this condition the threshold for "abnormally low" is often selected to be the 2.5th, 5th or 10th percentile of the population fT4 distribution. Because the BBDR model can be calibrated to any given percentile, but does not predict the distribution of fT4 levels, it was necessary to derive a fT4 distribution to identify a hypothyroxinemic threshold. EPA assumed a lognormal distribution with a Geometric Standard Deviation based on 2 to 3 studies depending on the gestational week. There is uncertainty regarding the true fT4 levels at various percentiles in the distribution around the median output from the BBDR model. For example, some of the analyses show larger unit changes with increasing percentiles of fT4 in most analyses (See tables 24, 30, 31, 32, 33

ED_005043_00063236-00010

and Section 6.5.6 of the MCLG Approaches Report). Please comment on the assumptions, strengths and limitations of the derived fT4 distribution for the purposes of this analysis.

14. Please comment on the strengths and limitations of the two-stage approach versus the alternative population-based approach to inform the derivation of an MCLG.

15. EPA has developed a two-stage approach linking the revised BBDR model results with quantitative information on neurodevelopmental outcomes from epidemiological studies. Please comment on the utility of the this two-stage approach for predicting potential impact of perchlorate exposure in early pregnancy on neurodevelopmental outcomes in the population at varying levels of iodide intake. Please comment on whether there are better strategies for estimating the potential impact of perchlorate exposure in early pregnancy on neurodevelopmental outcomes that are likely to be more scientifically defensible than the approaches presented (e.g. Appendix C estimates IQ impact directly from perchlorate exposure using Steinmaus et al. and Korevaar et al., or potentially some alternative studies). If an alternative approach would be more appropriate, please outline specifically how the approach might be developed given the current available state-of-the-science and data.

DRAFT

ED_005043_00063236-00011

III. GENERAL IMPRESSIONS

Hugh A. Barton, Ph.D.

The draft document and appendices are generally well written and present a sound approach to address the issue of assessing the potential neurodevelopmental impacts of perchlorate exposure during early pregnancy as a sensitive developmental window. The approach is consistent with the recommendations of the 2012-2013 EPA SAB Committee report. That report recommended elaborating the PBPK/PD model to include hormonal changes that would arise in response to perchlorate inhibition of iodide transport, the original endpoint for the model discussed in the 2012-2013 EPA SAB Committee report. It was further recommended that the predicted hormonal changes be linked with dose-response information describing the relationship between altered thyroid hormone concentrations and effects on neurodevelopment.

The current document describes just such an approach, modeling iodine and perchlorate pharmacokinetics, their competitive interaction at the iodide transporter, and the consequences for circulating maternal thyroid hormone concentrations including feedback via TSH and pregnancy induced changes due to hCG. This PBPK/PD model, tested against available information in the literature, is then used to predict impacts of perchlorate on thyroid hormone levels. These levels are then related to expected changes in neurodevelopment based upon published literature describing these outcomes in relation to thyroid hormone levels.

This approach, while it has uncertainties that are described in the report, avoids the major uncertainties of animal to human extrapolation if toxicological studies were proposed as the basis for the MCLG and those noted briefly in a later paragraph from using a simpler approach adjusting the RfD for body weight and drinking water consumption at different life stages. The modeling approach proposed also allows assessment of potential effects of perchlorate in a sensitive window of development during which it would be unethical to carry out a controlled clinical study. This contrasts with the studies of inhibition of iodide uptake evaluated in healthy male and female volunteers, one of the important sources of data for this modeling effort along with epidemiological and observational human studies.

That said, this is a model of substantial complexity due to the pregnancy related changes in iodine and perchlorate pharmacokinetics and in the pharmacodynamics processes regulating thyroid hormone levels. Reading the documents, it is not easy to obtain a clear and thorough understanding of the model's ability to predict median population behavior as well as predict behaviors in the hypothyroxinemic tails of the distribution for pregnant women. Appendix A is much more technically demanding and required expertise in the relevant areas to understand much of the information. Section 1.3, describing the probabilistic analysis, was extremely difficult for this reviewer to read as this was not my area of expertise.

It is worth noting that while public reviewers are appropriately concerned about the uncertainties and potential limitations of this complex modeling approach, the range of potential acceptable drinking water levels (Health Reference Levels) derived using simple body weight and water consumption adjustments for different life stages is reported to be 1 – 47 ug/mL (p 1-4). It is easy to criticize any single approach and difficult to assess the degree of uncertainty across approaches. The simpler default type approach, for example, suggests bottle-fed infants need the

ED_005043_00063236-00012

lowest concentrations while pregnant and non-pregnant women are protected by similar water concentrations because they have similar body weights and drinking water consumption with no consideration of changing iodide needs due to pregnancy. EPA is long overdue in moving forward with public health protections for perchlorate, but may benefit from comparisons among these approaches as it does develop an MCLG.

Nancy Carrasco, M.D., M.S.

Perchlorate contamination of drinking water in the United States is a serious problem because of the deleterious health effects of perchlorate on thyroid physiology. The primary function of the thyroid gland is to biosynthesize and release the thyroid hormones (T_3 and T_4), of which iodine is an essential constituent. The thyroid hormones are master regulators of intermediary metabolism in virtually all tissues throughout life and play a critical role in fetal and early life—specifically, in the development and maturation of the central nervous system, skeletal system, and the lungs. Insufficient amounts of thyroid hormones in the early stages of development lead to mental retardation and stunted growth.

The first step in the biosynthesis of the thyroid hormones is the active transport of iodide (I^-) across the plasma membrane of the thyroid follicular cells. This process is mediated by a specialized plasma membrane transport protein, the Na^+/I^- symporter (NIS), which couples the inward "downhill" translocation of Na^+ down its electrochemical gradient to the inward "uphill" transport of I^- against its *electrochemical gradient.* The central consideration motivating the draft report and the entire effort by the EPA to protect the population from perchlorate contamination is that perchlorate interferes with thyroid function by acting as a competitive inhibitor of NIS, thus preventing I^-, to one or another extent, from reaching the thyroid. Crucially, perchlorate is not only a blocking inhibitor: it is actually a NIS substrate. NIS has a higher affinity for perchlorate than for I^-. It is worth noting that the revised NIS affinity constant for perchlorate reported by Schlosser is exactly the same as that reported by Van Sande *et al.* (2013), a paper that should be cited. Tonacchera *et al.* (2004) reported that the affinity of NIS for perchlorate is 30 times its affinity for iodide. Therefore, in the presence of substantial concentrations of perchlorate in the plasma, NIS will preferentially transport perchlorate rather than I^- into the thyroid, thus decreasing thyroid hormone biosynthesis. In short, NIS is the key molecule at the center of this draft report.

I am a trained physician, a biomedical scientist, and a member of the National Academy of Sciences. My main area of expertise is transport across biological membranes. In 1996, my group was the first to clone the cDNA coding for NIS [Dai et al. (1996) *Nature*], a transporter we have been investigating at the molecular level in great detail for 22 years. We have published over 100 original peer-reviewed articles on NIS and topics related to transport across biological membranes in leading international journals, and have remained at the forefront of NIS research worldwide. We have characterized NIS extensively, elucidated many of its mechanistic and structure/function properties, and intensively studied its regulation and its medical applications, including that NIS is expressed in the lactating breast [Tazebay *et al.* (2000) *Nature Medicine*]. Furthermore, we were the first group to report that NIS actively transports perchlorate, and that it transports it with a stoichiometry (1 sodium : 1 perchlorate) different from the 2 sodiums : 1 anion stoichiometry with which it transports iodide [Dohan et al. (2009) *PNAS*, Paroder-

ED_005043_00063236-00013

Belenitsky *et al.* (2011) *PNAS*]. My impressions, which are informed by these qualifications, are as follows.

Overall, the report was carefully prepared, and it makes significant progress towards the goal of informing the EPA in its effort to derive a maximum contaminant level goal (MCLG) for perchlorate in drinking water. I sincerely commend the authors for what they have accomplished. For example, the report successfully summarizes the available papers on the effect of maternal hypothyroxinemia on the progeny. However, the report, especially in its sections that primarily deal with NIS and the effect of perchlorate on NIS, suffers from the following significant shortcomings: 1. the information presented is sometimes not accurate; 2. the presentation of both concepts and data is sometimes unclear; 3. numerous statements are made without being substantiated by proper references or, sometimes, by any references at all; 4. in many cases, where references are provided, these references are not the most relevant or the most appropriate; and 5. there is a general tendency to use references without regard to their true scientific value; for example, some of the articles cited present conclusions that were reached using outdated techniques that have now been shown to be invalid, and other articles cited are reviews rather than primary research papers, so the actual evidence for the relevant statements is missing altogether. Specific examples of these problems, drawn from throughout the text, are given below (under *III. Specific Observations*). Finally, as a result of these shortcomings, not all the conclusions reached in the report are sound. To give but one example, I am not aware of any evidence of NIS-mediated I^- transport activity in the skin or in erythrocytes, but both of these purported transport processes are nevertheless mentioned in the report as if they had been conclusively established to exist. My impression is that, although the authors of the report made a serious effort to provide evidence from the scientific literature to support their statements, they had no actual longstanding familiarity with the relevant literature on NIS. As a result, several key and seminal original research papers directly germane to the report were not mentioned, while papers with little bearing on the subject at hand or reporting on experiments carried out using outdated or discredited approaches were included.

Jonathan Chevrier, Ph.D.

I commend EPA for engaging in such a complex and ground-breaking enterprise in developing this two-stage BBDR model. The analysis and report were carefully and thoughtfully put together. The idea of using data from physiological parameters combined with epidemiological data in the development of a MCLG is certainly conceptually interesting and would be expected to be of greater value than using the fraction of a no-observed adverse effect level (NOAEL), as is commonly the case. However, this report demonstrates the difficulty of developing such models in a context in which much uncertainty remains. While there is convincing evidence that perchlorate affects circulating fT4 levels and that low fT4 during early pregnancy is associated with impaired neurodevelopment, the parameters underlying these effects are uncertain. Without being an expert in BBDR modeling, my impression was that the model was well thought through and the decisions that were made were well-supported. However, one question remained, which is whether uncertainty in fT4 prediction for each perchlorate exposure level had been quantified. My understanding is that Monte-Carlo types of analyses are generally run on such models to evaluate this uncertainly and I would have expected this to be carried over to the analysis of effects on neurodevelopment but this appeared to be missing. It is also unclear to

ED_005043_00063236-00014

me as to how the model can be validated. This said, my main concern is that the model predicts larger effects among women with higher fT4 levels than those with low fT4. This goes against what would be expected (effects should be stronger at the lower end of fT4), which suggests that issues remain with the BBDR model. My understanding is that this surprising result could be due to the fact that fT4 was assumed to be log-normally distributed. This goes against my own observations and what I have seen in the literature for populations other than first-trimester pregnant women. Although the distribution of fT4 could presumably be different in this population, not all studies reviewed by EPA reported log-normal distributions. In addition, these studies used immunoassays to measure fT4, some of which have been shown to be affected by the concentration of T4-bound proteins. Since the concentration of T4-bound protein changes as pregnancy progresses, fT4 measures from these studies may have been biased. It is unclear to me whether this may explain the skewed distribution of fT4 reported by some studies but this does question unexpected findings. It seems to me that one way or another the BBDR model needs to be adjusted so that its prediction agrees with current knowledge; and it would be useful to see results of the two-stage approach if a normal distribution of fT4 was assumed. Note also that I wonder if the method used to "average" the geometric standard deviations was correct (see comments below). Finally, the lack of usable epidemiologic data that is similar enough that it could be meta-analyzed and the decision to rely solely on studies that generated statistically significant result limit the applicability of the two-stage approach. My overall impression is that the approach has merit but I wonder if the necessary data is available to apply it to this question. I am also unclear as to how the data would ultimately be used to derive a MCLG. This said, I want to make clear that, despite its limitation, I believe that the overall approach has ample merit and is a step in the right direction that ultimately should have a more solid scientific basis than the current approach based on NOAELs derived from animal studies.

Claude Emond, Ph.D.

Here, the goal of this work was to predict the concentration of perchlorate that will induce a significant reduction of the fT4, causing neurodevelopment issue for fetuses during development. Hypothyroxinemia in pregnancy is defined as the presence of a free thyroxine (FT4) value below the 2.5th percentile with the thyrotropin (TSH) level within the reference range. Here, EPA develops a BBDR model trying to relate the exposure of perchlorate to hypothyroxinemia during pregnancy. When we review the document, it is clear to me that several parameters are very variable and not unique. Only trying to understand the relation between TSH and fT4 from the literature is so very different across-study that when plotted on a graph, the conclusion of this relation is difficult to make. It is probably based on the reserves of T4. Other physiologic causes, other than perchlorate, can also be implicated as exacerbating blood fT4 concentration levels in pregnant women. It is important to mention that the quality of the fT4 measurement can also explain the great variability observed in the literature. There is no question for me that the BBDR model is a gold standard for supporting different agencies in their decisions, based on biological plausibility. However, it seems that here, there is the complex harmonization of parameters derived using important statistical energy and fancy approaches. I have no doubt about the mode of action, based on a competition between perchlorate and iodine on the NIS transporters, but I am not sure that we have all the accuracy requested to conduct a risk assessment based on this complex model. The team who worked on this model put in a lot of effort and they are certainly the best in this field to respond to this

ED_005043_00063236-00015

complex question, but I am not convinced that we have a mature model for this task, mostly based on the data available and the complexity of the physiologic change during pregnancy.

Dale Hattis, Ph.D.

Overall EPA has done a creditable job in this analysis. I do have some suggestions for improvement, as outlined in my responses to the charge questions below.

Angela M. Leung, M.D., M.Sc.

The current report provides a complex analysis of the potential effects of low-level environmental perchlorate exposure in women during early pregnancy and their offspring during childhood, and represents an immense amount of work. Compared to the model reviewed in Jan 2017, the incorporation of early pregnancy and the hypothalamic-pituitary-thyroid axis feedback loop into this model is a much more physiologic and relevant assessment of exposure effects in a particularly vulnerable population subgroup and takes into account known compensatory mechanisms resulting from low iodine and/or thyroid hormone levels. In addition, the current model utilizes an exhaustive review of recently published literature (2000-2017) regarding the relationships between maternal hypothyroxinemia during early pregnancy and neurodevelopmental outcomes among their offspring, although only five studies resulting from this search were used for the model.

The current report summarizes an approach based on two stages:

- The first stage summarizes a revised BBDR model, regarding the relationships between iodine status and thyroid hormone production in women of childbearing age, in order to predict the potential effects of maternal perchlorate exposure on maternal thyroid hormone production during early pregnancy.
- In the second stage, the extensive presentation of summaries and key findings of the 15 studies meeting criteria for Group 1 (i.e. studies that evaluated maternal serum FT4 concentrations as a continuous variable during early pregnancy and any variety of offspring neurodevelopment outcomes) offers a detailed look at the most rigorous available studies on this topic at present. These studies were further restricted into the five which had reported a significant adverse effect of neurodevelopmental outcomes in offspring born to hypothyroxinemic pregnant women (thus not studies evaluating perchlorate exposure) to inform the derivation of a perchlorate maximum contaminant level goal (MCLG). The numerous other studies in the literature on this topic were not included as they either reported non-significant findings, did not assess maternal serum FT4 concentrations as a continuous variable, or were not intended to examine offspring neurodevelopmental outcomes.

As none of the five studies in the first approach were based in the U.S. but more importantly, does not provide extensive information regarding maternal iodine status, the report also presents an alternative population-based approach to determine the proportion of pregnant women in a perchlorate-exposed population who would be at risk for having offspring with an adverse neurodevelopment outcome, based on a given steady state of low iodine status.

ED_005043_00063236-00016

Overall, the current report is extensively detailed and generally improved from that discussed in Jan 2017, although the clarity of the writing could still be improved to be relevant for a broader readership, and there remain certain circular redundancies of language that could be addressed to make the report much more concise and overall readable. The charge questions as below were also at times overlapping in nature and leaned more toward model concepts; they may have been better phrased upon consultation with perhaps a more multidisciplinary group of experts.

Although the concepts of the overall model are biologically plausible, I have noted several areas, as below, to potentially strengthen key clinical concepts used to inform the model. My comments are based on my background and perspective as a clinical endocrinologist/thyroidologist with clinical research interests in iodine nutrition, thyroid dysfunction, and thyroid disruptor exposures during pregnancy, post-partum, and early childhood.

Stephen M. Roberts, Ph.D.

There are several important improvements in the BBDR modeling and the accompanying report from the version reviewed in January 2017. Addressing the first trimester fetus as a sensitive life stage, incorporation of a TSH – thyroid hormone feedback loop, extension of the modeling to include quantitative relationships between thyroid hormone effects and neurodevelopmental outcomes, much improved presentation of results and discussion of uncertainties, and overall clarity of presentation are among the most significant changes. The rationale for key decisions is clearly explained and supporting information/data are accurately presented. Overall, the conclusions are sound and the report provides an excellent means to evaluate the scientific strengths and limitations in two proposed approaches to developing a MCLG for perchlorate in drinking water.

Joanne F. Rovet, Ph.D.

Having reviewed the previous draft of BBDR Model Report for Perchlorate in Drinking Water (2016/2017), I find the current version far improved and much clearer in its presentation. In fact, it was a pleasure to read. Furthermore, the current extended version takes into account many of my earlier concerns, particularly: not modelling the HPT axis, not considering the early-in-pregnancy stage, poorly articulated downstream endpoints, use of old references, quality of presentation of results, and poor organization of report itself. Most of these issues have been satisfactorily addressed in what now appears to be a completely overhauled set of processes. The current model is bifold using both former BBDR modeling procedures to extrapolate maternal early gestational free T4 levels from varying perchlorate exposures in a low-iodine environment and using the current epidemiologic literature on offspring outcome following maternal hypothyroxinemia exposure to extract losses in child IQ or alternative endpoints. In the ultimate analysis, potential losses from varying perchlorate levels are individually tabulated according to findings from the five best papers. The writer(s) show an excellent understanding of how to manipulate a massive amount of empirical evidence in order to present cohesive and convincing arguments. This is very impressive.

ED_005043_00063236-00017

However, I still have a number of concerns, particularly the loss of any evidence and specifications for the other critical life stages, namely the later-stage fetus and the breast- versus bottle-fed baby. Granted, large-scale cohort studies of the necessary scenarios for these life stages are not as readily available as they are for those earlier in pregnancy to allow the modelers to derive the necessary numerical information for conducting the second phase of modelling, at least some attempt should have been made to estimate what is happening at these times during development. This is relevant because the brain continues to undergo thyroid hormone-dependent development past the second trimester and for some aspects of cognition and behavior, this latter development has a greater impact on overall life functioning. Note, I don't believe it was ever the intention of the former group of reviewers to remove these life stages.

Despite the excellent quality of presentation of Volume I, I was disappointed in its ending with a lack of summary and take-home message. I thought that some attempt might have been made to better combine the findings of the 5 studies into one set of data (e.g., using standard scores) and to better catalogue in a summary table the findings from remaining Group 1 studies as well as those from the other groups. I did think the author(s) at times got bogged down in the details of the paper. Furthermore, I would have liked the author(s) to discuss the clinical significance of the findings (and maybe even monetary costs); even though the effects were significant, their size was not large.

Notably, too, some critical papers were not discussed, particularly the CATS study findings and the paper by Taylor from this group on perchlorate and the new Pop paper that examines trajectories of maternal hypothyroxinemia throughout pregnancy as a critical factor. Along these lines, I wonder too why the studies measuring maternal TSH primarily were disregarded as this would be at least a marker of maternal thyroid hormone insufficiency to which the fetal brain is exposed. Finally, I found the discussion of thyroid and the brain to be very cursory and based on old literature and I think the author(s) understanding of pregnancy and the fetal compartments is a bit weak.

DRAFT

ED_005043_00063236-00018

IV. RESPONSE TO CHARGE QUESTIONS

Question 1. General Questions: Please comment on the appropriateness of focusing the current evaluation on perchlorate's potential impact on the fetuses of hypothyroxinemic pregnant women during early gestation for the purposes of informing a perchlorate MCLG.

Hugh A. Barton, Ph.D.

The focus on the fetuses of hypothyroxinemic pregnant women during early gestation is completely appropriate and consistent with the recommendations in the US EPA SAB report from 2012-2013. The January 2017 peer review of the PBPK/PD model for end of third trimester and post-natal lactational periods also identified that the literature linking altered thyroid hormone levels with neurodevelopmental impacts was largely limited to consideration of first trimester. Thus, this model addresses the recommendations of that peer review.

Nancy Carrasco, M.D., M.S.

Yes, I agree that it is appropriate to focus on perchlorate's potential impact on the fetuses of hypothyroxinemic pregnant women during early gestation for the purposes of deriving a perchlorate MCLG, because these fetuses are the most vulnerable subjects and the most likely to suffer serious and irreversible intellectual damage if exposed to perchlorate. Therefore, a perchlorate MCLG that protects these fetuses will ensure that other vulnerable populations are also protected.

Jonathan Chevrier, Ph.D.

Fetuses of hypothyroxinemic pregnant women is a population that is likely to be particularly vulnerable to the effect of chemicals on thyroid function. Early gestation, when fetuses cannot produce thyroid hormone and thus depend on thyroid hormone of maternal origin for normal development is also likely to be a sensitive developmental period. Focus on this population and developmental stage is thus highly relevant.

Claude Emond, Ph.D.

The description of the hypothyroxinemic pregnant women is the major issue, as well as the major window of sensitivity. This recommendation was also formulated by the SAB in 2017. I believe it was justified that the EPA requested to do the analysis for the first and second stages of pregnancy as well.

ED_005043_00063236-00019

Dale Hattis, Ph.D.

This seems reasonable; however, the effects of choosing various different degrees of iodide deficiency should be evaluated and reported. I would say that in general that a range for relatively conservative choices of thyroid deficiency should be made, including the 5th, 2nd, 1st, and possibly 0.1 percentiles of the US population, as projected from reasonably representative data for chronic exposures (acute effective one day exposure and/or blood level information from NHANES may need modification to achieve this goal). To do this, studies should be sought of the day to day within-individual variability of blood iodide levels.

Angela M. Leung, M.D., M.Sc.

The current report's focus remains on hypothyroxinemia, similar to the previous report discussed at the Jan 2017 meeting. However, the current report has now shifted to the offspring of women who were hypothyroxinemic during pregnancy, particularly during the first trimester, thus marking a change to an earlier insult, compared from the previous report that was primarily based on hypothyroxinemia during the post-partum period (among lactating women, breastfed infants, and formula-fed infants).

The focus on low maternal serum FT4 concentrations in early pregnancy, rather than another measure such as elevated maternal TSH concentrations, was recommended by the EPA's Science Advisory Board (2013) as the preferred marker of maternal thyroid hormone status in pregnancy. The pros and cons of utilizing hypothyroxinemia as the preferred marker of exposure were summarized at the previous meeting, and these remain the same now. These primarily included the inability to regard hypothyroxinemia in pregnancy as an independent clinical entity, but which has been demonstrated in recent literature to be associated with adverse offspring neurological outcomes.

The shift in the current report to focus on offspring neurodevelopmental measures is appropriate and marks an improvement from the previous report that assessed only serum FT4 concentrations in lactating women and infants. The current understanding of available literature suggests that these outcomes, which may be long-lasting and extend well into adulthood, are the results of low iodine status and/or thyroid hormone levels during mostly early pregnancy.

However, perchlorate exposure is of course not limited to women during early pregnancy. Notably, the lactation sub-model in the previous (Jan 2017) report has been eliminated in the current report. Although the primary focus should be early pregnancy, the early postpartum period represents a still important period of continued neurodevelopment and can be considered a secondary focus of exposure important for lifelong adverse outcomes, including neurocognitive measures. As noted in the Jan 2017 report, there are available data regarding perchlorate content in breastmilk and infant formula, albeit those should also be interpreted with their own limitations as per my previous comments.

ED_005043_00063236-00020

Stephen M. Roberts, Ph.D.

In their 2013 report, the SAB recommended using a PB/PK-PD (BBDR) approach in developing a MCLG for perchlorate in drinking water, and that the EPA include thyroid hormone changes during sensitive life stages for neurodevelopment, specifically mentioning fetuses of hypothyroxinemic pregnant women and infants and neonates exposed to perchlorate through breast milk or water-based formula. The initial BBDR modeling conducted by the EPA, peer-reviewed in January 2017, included these sensitive life stages, although modeling during pregnancy was limited to near term. Comments from the January 2017 peer review meeting strongly recommended that the first trimester of pregnancy be included as a sensitive life stage. The modeling effort currently reviewed is responsive to this recommendation, and in fact focuses on this life stage exclusively. The report explains that the epidemiology supporting a relationship between maternal thyroid hormone levels and neurodevelopmental outcomes is stronger for fT4 in the first trimester than later stages of pregnancy (see page 3-3). In fact, the report states, "This was confirmed by the results of EPA's literature search (summarized in Section 5) which found limited to no data regarding altered thyroid hormone levels and subsequent neurodevelopment effects on life stages other than early pregnancy." (page 1-5). The absence of data to credibly extend the BBDR modeling to neurodevelopmental outcomes for other life stages makes the decision to focus on early pregnancy appropriate in my opinion. However, it leaves unresolved the status of the other sensitive life stages — specifically, infants and neonates exposed through breast milk or water-based formula. Are they assumed to be less sensitive, and thus protected by a MCLG developed based on the first trimester fetus? If so, what information is available to support that assumption? Or is there simply not enough data to indicate the comparative sensitivity of the other life stages? If that is the case, it creates an uncertainty in MCLG development that merits additional discussion.

Joanne F. Rovet, Ph.D.

It is important that this period of development is examined, but not to the exclusion of the other sensitive periods. It is really a matter of convenience as the bulk of the cohort studies obtained maternal data at these times. I would have liked a better justification of why this period (and this period alone) is so critical. Bernal has recently shown that cerebral cortex neurogenesis takes place during this window. Perhaps some emphasis on this would rationalize this focus. However, the author(s) must be clear that further critical aspects of brain development are occurring in later windows and they are thyroid-hormone dependent. Perhaps incorporate some of the congenital hypothyroidism findings and some of the newborn screening (normal) results, especially if these were used as controls in neurodevelopmental studies. Perhaps too, include summarized findings of the studies on transient hypothyroxinemia of prematurity including those by this reviewer. This work covers the late-in-pregnancy sensitive period.

ED_005043_00063236-00021

Question 2. General Questions. Please identify any additional peer-reviewed studies that could inform the BBDR modeling or the quantitative relationship of thyroid hormone levels to neurodevelopmental outcomes. If an alternative study data set would be more appropriate, please outline how such data might be used.

Hugh A. Barton, Ph.D.

Not aware of any additional studies.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

I am not aware of studies other than those used or otherwise mentioned in this report.

Claude Emond, Ph.D.

I did not find any additional peer-reviewed studies that would add significant information to challenge this work.

Dale Hattis, Ph.D.

I didn't come across any.

Angela M. Leung, M.D., M.Sc.

For the current report, a comprehensive search was performed of published studies regarding the relationships of serum thyroid hormone concentrations and neurodevelopmental outcomes. However, the search was restricted to studies published in 2000 and later. This approach omits the important study by Haddow et al. (NEJM, 1999; PMID: 10451459), which in fact did measure maternal serum TSH, TT4, and FT4 concentrations (erroneously stated in the current report that serum TT4 and FT4 were not measured) and correlated to their offsprings' neuropsychological test scores at ages 7-9. This was one of the first reports to demonstrate an adverse effect of maternal hypothyroidism during pregnancy on childhood neurocognitive outcomes, is considered a seminal article regarding this topic, and should be included.

ED_005043_00063236-00022

Stephen M. Roberts, Ph.D.

I am not aware of any additional peer-reviewed studies that would be useful for the BBDR modeling or in establishing a quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes.

DRAFT

ED_005043_00063236-00023

Question 3. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy</u>. Please comment on the assumptions, strengths and limitations of methods and parameters by trimester for:

Question 3A. Determing the quantitative relationships between oral intake and serum levels of perchlorate during pregnancy under continuous exposure assumptions, and

Hugh A. Barton, Ph.D.

Model simulations compare well with data for non-pregnant women (Section 2.1 in Appendix A) and males. Adjustments of physiological parameters are made for pregnancy, so in the absence of other data, it is appropriate to assume that the model reasonably predicts perchlorate pharmacokinetics during pregnancy.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

The method for determining the relation between oral intake and serum levels of perchlorate appeared appropriate to me. BBDR modeling being outside of my area of expertise, I do not feel that I can comment further on the assumptions, strengths, and limitations of the method and parameters.

Claude Emond, Ph.D.

It is reported in the document that "Several short-term (two-week exposure duration) studies have reported that exposures ….. decreases in iodide uptake, <u>but not with changes in levels of thyroid hormones in the blood"</u> (V1, page 1-2, p15) This is because the reserve of T4 is relatively high. What would the dose that will really impact the homeostasis and spent the dose causing a hypothyroxinemia?

Dale Hattis, Ph.D.

The relationship between external exposures to perchlorate and serum levels of thyroid hormones in the current EPA analysis appears to be primarily inferred from a recent paper of Steinmaus et al. (2016). This is a good paper based on extensive relevant observations of the association between serum thyroid hormone levels and urinary perchlorate observations (the latter, a good indicator of recent exposure to perchlorate).

ED_005043_00063236-00024

Unfortunately, the Steinmaus analysis choses to use a log-transform of the urinary perchlorate in its regressions, e.g., serum thyroid hormone concentration in the blood (that is, total T4, fT4, and the related variable TSH) = Log10(urine perchlorate) + other regression variables.

My past experience is that there are few, if any, biological mechanisms that lead naturally to an expectation of a log-linear dose response relationship. Instead, mechanistically based Michaelis-Menten enzyme kinetics leads more naturally to another mathematical form:

Effect = Emax*[C]/(Km + [C]

Where [C] is the substrate concentration (i.e., perchlorate in this case), Emax (change in thyroid hormone concentrations) is the maximum effect that can be produced at the the limit of high [C], and Km is a constant

For convenience in regression analysis, the Log(10)[C] in the Steinmaus et al. (2016) regression analyses could be replaced by:

[C]/(Km + [C]),

where an optimal value of Km for the regression can be found, by trial and error, using multiple runs of the regression with different candidate values of Km. This optimality can be judged by maximizing the R squared statistic.

Log transformations of both dependent and independent variables have a long and hallowed tradition in analysis of epidemiological data. However, while there can be some statistical benefit in normalizing a dependent variable by log transformation, this does not carry forward to the domain of independent variables. There can be no general expectation for no improvement in the properties or accuracy of regression analysis from making the distribution of an independent variable closer to normal. Instead, the analyst will improve the description of the real causal relationship most by having the fitted equation resemble as closely as possible the real causal relationship that gave rise to the observations.

Angela M. Leung, M.D., M.Sc.

The perchlorate sub-model in Figure 4 of the main report, as well as Section 1.2 of Appendix A, were reviewed. Appendix A states that perchlorate ingestion is not metabolized, thus is assumed to be 100% absorbed and equal to the steady state delivery to plasma. Available literature appears to support this and demonstrates that perchlorate is excreted intact in the urine with 95% recovery within 72 hours (Soldin et al, PMID 11477312). Given this, the assumption that nearly 100% of ingested perchlorate will circulate in plasma unchanged appears to be appropriate.

ED_005043_00063236-00025

Stephen M. Roberts, Ph.D.

The perchlorate sub-model treats perchlorate as being delivered directly to the central compartment (no transformation in the GI tract and 100% absorption). This simplification could affect simulation of short-term perchlorate kinetics, but is less of an issue for longer-term model predictions most relevant to the BBDR modeling. Modeling has been strengthened by the addition of a number of refinements, including protein binding of perchlorate in blood and distribution into red blood cells. One limitation in modeling perchlorate kinetics in pregnancy is the absence of suitable kinetic data from pregnant women. As a result, data from non-pregnant women and men had to be used for comparison with model predictions. Changes in the clearance rate of perchlorate during pregnancy were estimated from an empirical relationship between gestational age and glomerular filtration, and the relationship between glomerular filtration rate and iodine clearance. These approaches to the absence of PK data from pregnant women are reasonable but contribute to uncertainty in perchlorate blood concentration predictions.

Joanne F. Rovet, Ph.D.

While Figure 4 seems reasonable to me from the point of view of the mother, it does not account for the fetus and for the fetal brain, which ultimately need their thyroid hormone. There is no accounting for the different sacs and how perchlorate may interfere with thyroid iodide to the fetus via the coelomic sac (earliest pregnancy) and amniotic sac (later). Similarly, there is no system that models thyroid hormone from the mother to the fetal brain and into the brain via the blood-brain barrier (to cortex) and choroid plexus (to subcortical regions and posterior cortex). It is said that NIS receptors are found in the choroid plexus, so what happens if these are blocked?

DRAFT

ED_005043_00063236-00026

Question 3. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy</u>. Please comment on the assumptions, strengths and limitations of methods and parameters by trimester for:

Question 3B. Estimating statistical distributions of specific biochemical parameters that determine serum perchlorate concentrations, urine clearance of iodide and perchlorate, and thyroid iodide uptake for purposes of estimating the effect of environmental levels of perchlorate on maternal fT4 concentrations.

Hugh A. Barton, Ph.D.

Estimation of statistical distribution is not this reviewer's area of expertise. It was not entirely clear how the use of some parameters as a specified lower percentile, e.g., CLFUP as 2.5th percentile value, fit together with the distributional aspects.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

The methods used to estimate the distribution of parameters that determine serum perchlorate concentrations, urine clearance of iodide and perchlorate, and thyroid iodide uptake appear adequate. Again, BBDR modeling being outside of my area of expertise, I do not feel that I can comment further on the assumptions, strengths, and limitations of the method and parameters. However, I note that it appears that the literature was searched systematically for published data necessary to identify the distribution of parameters and the relation between variables. Whenever possible, raw data was requested to perform additional analyses. It is apparent that decisions were made after careful evaluation.

Claude Emond, Ph.D.

This is a very sophisticated approach, using all those statistics, but in the end, I am not sure about the improvement (advancement) of these sophisticated approach. I hope we will have an explanation during the meeting.

Dale Hattis, Ph.D.

See comment to Question 3A.

ED_005043_00063236-00027

Angela M. Leung, M.D., M.Sc.

I reviewed the values summarized in Table 1, but this is not my area of expertise and cannot comment further.

Stephen M. Roberts, Ph.D.

Variability in maternal fT4 concentrations was estimated based upon studies with fT4 data from 12, 13, and 16 weeks of gestation. Although the number of available studies was small (3), the use of variability data from human subjects is an important strength. Data were assumed to be lognormally distributed, and a geometric standard deviation (GSD) was used to quantify variability. As the report points out (page 4-6), although the data were right-skewed, a distribution other than lognormal may better describe the variation in fT4. Time and resources permitting, it would be useful to explore other distributions, as the population variability in fT4 is important in predicting perchlorate effects at various percentiles.

Joanne F. Rovet, Ph.D.

This is beyond my competence.

DRAFT

ED_005043_00063236-00028

Question 4. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy</u>. Please comment on the assumptions, strengths and limitations of the uncertainty analyses of the parameters, particularly with regard to availability of data supporting parameter assumptions.

Hugh A. Barton, Ph.D.

No comment.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

The strategy used to consider the uncertainty and the variability was correctly applied. They analyzed all the parameters as mentioned on page A-97 (103 in pdf). The outcome was the variation of the fT4. Here they reported only parameters with relative change higher than 0.1, which is fine.

Dale Hattis, Ph.D.

The document has a quite extensive qualitative discussion of the uncertainties of the analysis. It could be improved by drawing some quantitative inferences about how large the uncertainties from different sources are likely to be.

Angela M. Leung, M.D., M.Sc.

The report described several uncertainties in Section 3.5:

- **Placental and fetal iodine and thyroid hormone content**: Page 43 of the report states that the absolute contribution of iodine and thyroid hormone stores in the placenta and fetus toward those in the mother are likely insignificant, thus there are not separate placental and fetal sub-models. I agree that this is likely appropriate, since the fetal thyroid does not begin to develop structurally until approximately 10-12 weeks of

ED_005043_00063236-00029

gestation, and remains very small in size (relative to the maternal thyroid) with likely very little iodine and thyroid hormone content throughout gestation.

- **Iron deficiency**: Page 43 describes the potential impact of iron deficiency on hypothyroxinemia as an uncertainty. Although iron deficiency anemia is the most common cause of anemia during pregnancy, we do not seem to observe hypothyroxinemia commonly in the clinical setting among women with iron deficiency. I would agree that maternal iron deficiency is unlikely to be a significant contributor for the purposes of the model and does not have to be accounted for. Of note, the 2016 ATA pregnancy guidelines also do not mention iron deficiency.
- **Coexposures**: Page 45 states the potential uncertainties of the model resulting from coexposures to other environmental and dietary thyroid disruptors. Accounting for wide number of these unmeasured substances is impossible, and thus it is appropriate to leave this issue as a limitation of any exposure model, as was stated in the report to be present also in the NHANES datasets. One consideration, however, is thiocyanate as the one exposure with sufficient available data to likely further improve the perchlorate model (see my comments to Question #8).
- **Competitive effect at low perchlorate concentrations**: Page 45 describes the uncertainty of the model based on the effect perchlorate on iodine uptake as mediated by NIS at low perchlorate levels. It is appropriately stated that current understanding demonstrates no additional magnification of this effect even at lower perchlorate concentrations.
- **Potentiation of other thyroid disease**: Page 46 lastly describes the potential uncertainty of environmental perchlorate exposure on potentiating the development of other thyroid diseases, such as Hashimoto's thyroiditis. Although this is certainly possible, current understanding is limited to lacking on this topic, thus it is appropriate to leave this as an uncertainty of the model.

Stephen M. Roberts, Ph.D.

A semi-quantitative analysis of uncertainty and variability of the parameters was conducted through a Local Sensitivity Analysis presented in Appendix A. Although ranges of values were not determined in a statistically rigorous way, the analysis nevertheless provides a rough estimate of the range of potential values compared with the central estimate. This analysis is adequate for the purposes of the report.

Joanne F. Rovet, Ph.D.

I am not too sure if the TSH feedback loop is properly incorporated and how, but I may be wrong. Note the Hadlow paper shows sex and age differences. Were these values incorporated into the model. Are the various transporters incorporated into the model?
Are individual differences in sensitivity of TSH incorporated into the model, as mentioned on page 3-9. What about the assumption (mine) that continued exposure to low iodine and perchlorate may put the hyothalamus and pituitary into overdrive and create a form of resistance, perhaps leading to later hypothyroidism, which can happen during pregnancy when the system is

ED_005043_00063236-00030

stressed. Is this being accounted for in the model? Interestingly, these cases were eliminated in the second part of the analysis.

I am not too sure what is meant by the statement "Increased urinary clearance of both iodide and perchlorate during pregnancy (why?), described by the model, have the conflicting effect of both reducing … so these two components of pregnancy-related changes will cancel each other out to some extent".

DRAFT

ED_005043_00063236-00031

Question 5. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy</u>. Please comment on the utility of the BBDR model for predicting variability in fT4 levels in the population (e.g., percentiles for different thyroid hormone levels) at varying levels of iodide intake.

Hugh A. Barton, Ph.D.

Since changes in fT4 levels are a key output of the model, its ability to predict them for varying levels of iodide intake is important.

The comments submitted by American Water Works Association (AWWA), based upon a review by Gentry et al., states that these levels are not adequately predicted. In response to this concern, I undertook some review of the modeled median fT4 levels during pregnancy without perchlorate exposure. It is difficult to understand what is going on with different values ranging from about 10-15 pmol/L in different figures and tables at gestation weeks 12 – 16 (e.g., Fig A-57 14-15 pM; Table 2 10-11 pM for 170 ug/day iodide; Fig 5 ~10.5 pM). Since Fig A-57 represents data from studies and appears well simulated, it is not clear what is different in Table 2 and Fig 5.

Gentry et al. ran the model to compare results with three studies, and presumably their findings contributed to their comments that the model did not adequately predict. The problem for both the Steinmaus et al. 2016 study and the highest dose of Greer et al. 2002, was that the model under predicted the extent of perchlorate-mediated changes, while for Tellez Tellez et al. 2005 predictions were consistent. Thus, it isn't clear that the model inadequately predicts, or if it does, it appears to be insufficiently responsive to perchlorate-mediated effects.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

I am not convinced at this stage of the relevance, usefulness, and resilience of this model to predict the influence of perchlorate to significantly reduce the concentration of fT4 in pregnant women.

ED_005043_00063236-00032

Dale Hattis, Ph.D.

See detailed comments on the variability analysis in my response to question 7 below. A priori I have no difficulty with the use of the model as now done in the document.

Angela M. Leung, M.D., M.Sc.

The model's incorporation of other factors, such as the TSH feedback loop and effect of bHCG, strengthens the ability to predict maternal serum FT4 levels, at varying levels of iodine intake. The model's estimation of dietary iodine intake is summarized in Appendix Section 2.2.1, which is based on a spot urinary iodine concentration collected from NHANES participants and adjusted for known or estimated daily urine volumes.

However, there can be substantial diurnal and day-to-day variations in urinary iodine concentrations in a given individual (Rasmussen et al, PMID 10359497). Given this, it is not surprising that the current report found no relationship between dietary iodine estimates and serum FT4 concentrations in the NHANES datasets. The accuracy of the iodine intake values is a limitation to the model predicting serum FT4 concentrations. Overall, the challenge is that individual iodine status is difficult/impossible to estimate; only population iodine status can more reliably be determined.

The present report can also consider the points made in the following article by Brucker-Davis and colleagues demonstrating no effect of iodine supplementation in later pregnancy (albeit later pregnancy) on serum FT4 concentrations (PMID 24847452), which was reviewed briefly for *Clinical Thyroidology* and *Clinical Thyroidology for the Public* as below:

https://www.thyroid.org/patient-thyroid-information/ct-for-patients/vol-6-issue-12/vol-6-issue-12-p-4-5/.

https://www.thyroid.org/wp-content/uploads/publications/clinthy/clinthy_v2510.pdf

Stephen M. Roberts, Ph.D.

As indicated in Figure A-57, the BBDR model predicts variability in fT4 levels as a function of iodide uptake reasonably well.

Joanne F. Rovet, Ph.D.

It seems reasonable, although I still had difficulty reading the simulation graphs (p3-11).

ED_005043_00063236-00033

Question 6. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy</u>. Please comment on the robustness, precision and sensitivity of the model, and how these factors affect the model's ability to predict changes in fT4 at low perchlorate doses. Consider whether a perchlorate dose range exists for which the modeling predictions would be highly uncertain.

Hugh A. Barton, Ph.D.

EPA provides a wide range of information on fits to different data sets and sensitivity analyses. Not surprisingly, the model fits some data better than others, but it is not obvious that there is a consistent problem in a specific area of biology or dose range. Gentry et al., in their comments for AWWA, question whether the model should be relied upon for small changes in model outputs (e.g., <1%), such as fT4. Given the variability in existing data and the complexity of the decisions involved in putting together this model, it does seem reasonable to be concerned that very small predicted changes in model outputs might be more difficult to characterize for how well supported they are compared to somewhat larger change (e.g. >1-2%).

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

My impression is that several parameters have been adjusted and statistically optimized because of missing measured parameters. However, even though we performed this optimization, we can see that the relation between TSH and fT4 are still compared to a cloud of data points from biomonitoring. The figures (Fig 5Vol 1, page 3-11; figure A-44 A-46 Vol2 page A-70), precise that the simulation of TSH showed that an increase of perchlorate exposure result in a decrease of fT4 resulting in an increase of TSH. Nevertheless, we can see that the model simulation curve is in the middle of a cloud obtained by biomonitoring of a dataset. Meanwhile, I am still thinking about what I observe if it is the best curve corresponding to the biological relevant or the reality is more variable and how confident I am with this prediction. The model is usable to determine the Maximum contaminant level goal (MCLG). However, more data need to be generated to improve the confidence of the predictability for this model.

ED_005043_00063236-00034

Dale Hattis, Ph.D.

I have no problem with the current treatment of this issue in the document. There is some reason for concern however about the accuracy of the current model at very low levels of iodide intake where the induction of TSH may or may not be accurately represented by the current model. There will clearly be some chronic reduction in internal stores of iodide and the response of the system under those conditions has not been clearly tested. However, low perchlorate dose levels do not, in my opinion, give rise to similar concerns.

Angela M. Leung, M.D., M.Sc.

- **Dietary iodine**: Comments as above in question #5.
- **Iodine intake in non-pregnant vs. pregnant women**: The results shown in Section 3.4 and Figure 5 show example outputs from the BBDR model of non-pregnant individuals and pregnant women. It is unclear to me whether the model takes into account the increased iodine need in pregnancy (extra 70 mcg/day), compared to non-pregnant adults (see Table 1 in Leung et al, PMID 22108279), that U.S. pregnant women are advised to be (albeit not uniformly) receiving (Alexander et al, PMID 28056690). Section 3.3 does state that the model adjusts for the increased serum T4 concentrations in pregnancy, for which the increased iodine need is one reason underlying this.
- I defer to the other reviewers regarding the remainder of the model.

Stephen M. Roberts, Ph.D.

As the report points out, data in humans with which to compare BBDR model predictions for perchlorate effects on fT4 are very limited. Appendix B shows a comparison of BBDR model predictions with fT4 data and perchlorate exposure from Steinmaus et al. Those comparisons show some difference in the closeness of the model prediction with Steinmaus et al. data with perchlorate dose, but overall the model appears to under-predict, substantially, changes in fT4 with perchlorate dose. There are some important limitations in this comparison due to limitations in the Steinmaus et al. study, including lack of concurrency in perchlorate exposure estimation and fT4 measurements.

Joanne F. Rovet, Ph.D.

One concern I had throughout the report is why perchlorate dose increases by 1 unit until 5 micrograms/kilo/day and then jumps to 10. Why?

ED_005043_00063236-00035

Question 7. BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy. The revised BBDR model incorporates a TSH feedback loop defined by an equation from Hadlow et al. (2013) (J Clin Endocrinol Metab, 98(7): 2936-2943), with an adjustment factor to match specific data sets or population percentiles, to describe the relationship between fT4 and TSH.

Question 7A. Please comment on the assumptions, strengths and limitations of this approach to incorporate a TSH feedback loop into the BBDR model.

Hugh A. Barton, Ph.D.

Appeared reasonable.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

Because TSH is a hormone, responsible for retro feedback, the production of T4 is essential in the BBDR model. The problem seems to be more the quality of the data showing an important variability make difficult to get a better accuracy of the. It also seems that threshold certainly seems implicated induced the reserved of T4.

Dale Hattis, Ph.D.

I agree that the interindividual variability distribution for fT4 should be presumed to be lognormal. However, the approach for combining estimates of variability from different datasets shown in Table 5 (p. 49) is not correct. Geometric standard deviations should never be simply averaged. Variances (the squares of the standard deviations) should be used as the basis for calculating weighted averages. In this case, because the GSD estimates from different data sets refer to lognormal distributions, the variances represent the variances of the distributions of the logarithms of the fT4 levels.

Delving into the detailed numbers provided in Table 5 requires some interpretation. Because the numbers in the second and third columns of the table are all less than 1, they cannot represent GSDs. My best guess is that they represent standard deviations of the logarithms of the

ED_005043_00063236-00036

underlying distributions of fT4 levels. Corresponding GSDs would have to be the anti-logs of these values, e.g. $10^{\text{table values in Columns 2-3}}$. Given this assumption/guess, Table A on the next page gives my inferences for combined log(GSDs) for the different cells in Table 5. (Results are expressed to many more significant figures than are warranted to allow precise replication of the calculations. The accompanying Excel spreadsheet shows the numerical derivation of these estimates.

It can be seen in the results in Table A that, as it happens, there are very small differences between these results of this corrected combination of lognormal distributions from the results provided in the initial Table 5 given in the document. Nevertheless, I believe it is important to correct the methodology and presentation of results and to revise the subsequent table based on the altered table 5 because EPA will not wish to provide a basis for later technical challenge to the policy-relevant risk estimates that will eventually be derived.

Table A
Recalculated Values for Table 5 Based on Combining Lognormal Variances Rather than GSDs

	Log Variance from 2.5th percentile estimate	Log Variance from 97.5th percentile estimate	Combined	Calc log(GSD) from 2.5th percentile estimates	Calc log(GSD) from 97.5th percentile estimates	Combined estimate of log(GSD)

Angela M. Leung, M.D., M.Sc.

It is appropriate for the revised model to include considerations of the hypothalamic-pituitary-thyroid feedback loop, in which serum TSH concentrations will be simulated based on predicted serum FT4 concentrations, for use in the feedback loops shown in Figure 4, specifically the action of TSH on thyroidal NIS.

However, the following assumptions should be further clarified: 1) the stimulatory action of TSH on NIS should also be in the perchlorate sub-model, since it is the same NIS in both the perchlorate and iodide sub-models; 2) the inhibition of perchlorate on NIS in the iodide sub-model should be technically from the perchlorate content in thyroid plasma, rather than NIS, in the perchlorate sub-model.

It should also be noted that there is some variation in the TSH feedback mechanism amongst individuals (i.e. there are likely not a discrete FT4 setpoint at which increased TSH is universally triggered).

ED_005043_00063236-00037

Stephen M. Roberts, Ph.D.

I have not yet formed an opinion on this question and look forward to discussion with other panel members during the face-to-face meeting in formulating my response.

Joanne F. Rovet, Ph.D.

This seems reasonable as this looks to be a good study.

DRAFT

ED_005043_00063236-00038

Question 7. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy.</u> The revised BBDR model incorporates a TSH feedback loop defined by an equation from Hadlow et al. (2013) (J Clin Endocrinol Metab, 98(7): 2936-2943), with an adjustment factor to match specific data sets or population percentiles, to describe the relationship between fT4 and TSH.

Question 7B. Noting the reliance on the Hadlow et al. (2013) study, please comment on whether there are other studies that should be considered and describe how they would improve the analysis.

Hugh A. Barton, Ph.D.

No comment.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

I am not aware of any other publication that might improve the analysis. However, if we look at Figure A-46, there is so much variability between studies that I am not sure about the plus value of this statistic. There seems to be a large uncertainty in this relationship. However, using only Hadlow is not enough, even if there are "data from over 150 thousand subjects". The correction added in the equation seem interesting, but using that we increase the uncertainty of the Hadlow equation.

Dale Hattis, Ph.D.

See comment to Question 7A.

Angela M. Leung, M.D., M.Sc.

The classic log-linear relationship between serum TSH and FT4 concentrations has long been recognized, which the Hadlow et al. article used to define this feedback loop in the current model does not support. The report does not sufficiently describe the reasons why this equation comprised of two sigmoidal curves was chosen to model the relationship between TSH and FT4.

ED_005043_00063236-00039

A commentary of the Hadlow article by Dr. Elizabeth Pearce was published in *Clinical Thyroidology* (https://www.thyroid.org/professionals/ata-publications/clinical-thyroidology/july-2013-volume-25-issue-7/clin-thyroidol-201325156-157/), which summarizes the strengths and limitations of this paper, as well as citations of three other papers (references 1-2) which can also be considered.

Stephen M. Roberts, Ph.D.

I am not aware of other studies that should be considered to improve the analysis.

Joanne F. Rovet, Ph.D.

Perhaps check out the CATS data.

DRAFT

ED_005043_00063236-00040

Question 7. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy.</u> The revised BBDR model incorporates a TSH feedback loop defined by an equation from Hadlow et al. (2013) (J Clin Endocrinol Metab, 98(7): 2936-2943), with an adjustment factor to match specific data sets or population percentiles, to describe the relationship between fT4 and TSH.

Question 7C. Please comment on the approach for characterizing inter-individual variability in relevant populations from which the epidemiological data were obtained.

Hugh A. Barton, Ph.D.

No comment.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

I do not feel qualified to answer questions 4-7 and prefer not to comment.

Claude Emond, Ph.D.

The variability is certainly the major influence affecting the level of confidence of the PBPK model. The improvement of the analytical method used in the identification of TSH, fT4, and total T4 should be included in the recommendation.

Dale Hattis, Ph.D.

See comment to Question 7A.

Angela M. Leung, M.D., M.Sc.

The report acknowledges several areas of potential inter-individual variability:

- **NIS**: It is reasonable to state that the degree of potential variation in NIS structure and/or regulation across individuals is unknown.
- **TSH response**: It is reasonable to state that there may be inter-individual variability in the magnitude of a TSH response following perchlorate exposure, due to the stated differences in genetics, subclinical thyroid dysfunction, age, gender, cigarette smoking, coexposures, and likely other factors. The acknowledgement that these are likely

ED_005043_00063236-00041

contributors, but which remain unable to be further built into the present model, is sufficient.

- There are also nonmeasured factors such as genetics and coexposures that may be important. Any variability in the above factors and others is best minimized with large epidemiologic datasets. Unless otherwise noted, it is a reasonable assumption that the datasets used to build the current model are appropriate.

Stephen M. Roberts, Ph.D.

I have not yet formed an opinion on this question and look forward to discussion with other panel members during the face-to-face meeting in formulating my response.

Joanne F. Rovet, Ph.D.

This represents a definite improvement in the approach. The authors have been very thorough and systematic. Their work here represents one of the best compilations of the field.

DRAFT

ED_005043_00063236-00042

Question 8. <u>BBDR Modeling to Predict Changes in Thyroid Hormone Levels in Early Pregnancy.</u> Since the observational thyroid hormone data that are used to calibrate the model derive from populations exposed to goitrogens other than perchlorate, EPA has made an assumption that the model parameters may implicitly account for exposures to these other goitrogens. As such, the exposure to perchlorate is assumed to be effectively added to this background goitrogen exposure as discussed in Chapter 3.5 of the report.

Question 8A. Please comment on the validity of this assumption and the extent of uncertainty associated with this assumption.

Hugh A. Barton, Ph.D.

This assumption appears reasonable because the responses observed in the human population reflect the full range of causes of population variability, e.g., genetics, life stage, co-exposures to goitrogens, and variations in iodide intake. While intellectually it would be interesting to understand the interplay among all these factors, it does not appear necessary for current purposes. For the responses to perchlorate to be substantially incorrectly attributed to perchlorate, it would have to be the case that the levels of perchlorate exposure were very highly correlated with exposures to other goitrogens.

Nancy Carrasco, M.D., M.S.

The topic of BBDR modeling and the fields of pharmacokinetics and pharmacodynamics are outside my area of expertise; I am therefore unable to comment on this topic.

Jonathan Chevrier, Ph.D.

This may be the case if one assumes that samples used in studies used to generate the data were representative of the U.S. population. This means that the distribution of all factors that could modify the relations between exposure to perchlorate and fT4/neurodevelopment should be similar in study samples as it is in the general U.S. population. Given the fact that most studies did not have a probabilistic sampling design, that most used non-U.S. population that may have different exposures to goitrogens, and considering the modest sample size of most studies used in this report, EPA's assumption is likely to be over-optimistic. EPA may want to consider applying a safety factor to derive the MCLG to account for exposure to other goitrogens.

Claude Emond, Ph.D.

No comment at this time.

ED_005043_00063236-00043

Dale Hattis, Ph.D.

This seems to me to be a reasonable assumption.

Angela M. Leung, M.D., M.Sc.

Please see my comments regarding exposures to other thyroid disruptors in Question #4. The assumption that the datasets used to calibrate the model also contained exposures of unaccounted substances is reasonable.

Specifically, however, thiocyanate is the one goitrogen that may deserve further consideration for incorporation into the model. Thiocyanate is a byproduct of cigarette smoke and present naturally in certain *Brassica* vegetables, thus is a potentially common and ubiquitous exposure. Like perchlorate, thiocyanate inhibits iodine uptake mediated by NIS, though with lower affinity. There are some limited but sufficient data regarding thiocyanate to potentially use in further strengthening the model's assumptions regarding coexposures. These data include measured thiocyanate exposures in various early pregnancy cohorts, including NHANES.

Stephen M. Roberts, Ph.D.

The assumption is valid — the issue is the extent to which the available data adequately reflect variability in exposure to other goitrogens. This is a source of uncertainty in the model, but not so great as to negate the utility of these data for model calibration.

Joanne F. Rovet, Ph.D.

I'm not too sure what this means.

DRAFT

ED_005043_00063236-00044

Question 9. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA conducted a three-step literature review, which identified 15 studies with information that could inform the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes.

Question 9A. Please comment on whether EPA has clearly identified the criteria to identify studies through each of the three steps of the literature review, and the adequacy of the strategy for conducting the literature search. Are these criteria scientifically supportable, and did EPA apply them properly?

Hugh A. Barton, Ph.D.

The strategy for the literature search and the criteria for categorizing the studies into three groups are clear and scientifically supported.

The search strategy initially appeared too narrow in that six additional references were added from the previous SAB review to the 49 identified through searching. Of the six, four were category 3 and thus found not to provide relevant information. Two were category 1, with one published in 1999 (before the 2000 – 2017 search period) and one in 2011, during the search period. Thus, the search appears to have been somewhat stronger than it initially appeared. But, if the search is updated, it may be worth considering whether other search terms or a broadening of the search time period would be beneficial.

Some commenters suggested that the criteria were not applied correctly in the determinations of categories, so EPA should review the decisions to insure they were appropriate.

Nancy Carrasco, M.D., M.S.

Although I am no expert on issues related to the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes, it seems to me that, yes, EPA has clearly identified the criteria for identifying relevant studies through each of the three steps of the literature review. The strategy for conducting the literature search appears to be adequate, to the best of my knowledge. I think the criteria employed by EPA are scientifically supportable and that EPA used them properly.

Jonathan Chevrier, Ph.D.

The literature review strategy is well-described, but some details are lacking. For instance, there is no information about the number of individuals who were involved at each step, whether more than one person reviewed the studies identified after running the searches (ideally there would be at least two people) and how disagreements were resolved.

The fact that some search strings were restricted to paper titles, while others were not, is somewhat puzzling and raises the possibility that some papers may have been missed. Google search can indeed generate an unreasonably large number of hits but PubMed is usually more

ED_005043_00063236-00045

restrictive when using boolean terms, which was confirmed to me when I used some of the search strings listed in the report. I also wonder why "thyroid" was not used as a search term. "T4" or "thyroxine" could miss some paper of interest.

Finally, the fact that ultimately only studies with significant results were considered does not seem appropriate. Such a strategy is likely to overstate the effects of perchlorate on neurodevelopment. It is important to note that statistical significance is a function of the magnitude of the association and sample size and so estimates from non-significant studies, though imprecise, still have value. Ideally, a summary estimate would be generated from the literature for different outcomes, but studies are not similar enough to combine estimates.

Claude Emond, Ph.D.

I think EPA did everything they could to extract from the literature all the data that were required from epidemiological studies.

Dale Hattis, Ph.D.

I have no difficulty and no suggestions for improvement of the document on these issues.

Angela M. Leung, M.D., M.Sc.

The EPA restricted the literature search to studies examining maternal serum FT4 or TT4 levels and offspring neurodevelopment published only after 2000 in order to focus on the most recent science. The Haddow 1999 study was excluded due to the year of publication, as well as the absence of maternal serum FT4 or TT4 levels in the study (the latter is erroneous though). Although it is reasonable to restrict by date of publication, the exclusion of studies that examined only maternal serum TSH concentrations may miss some important data. The Haddow study is a good example of a seminal piece of literature, critical toward a more complete understanding of this topic, that was excluded (or at least placed in Group 3) on this basis.

Overall, the search terms appear to be comprehensive in capturing the desired output.

Of note though, it is unclear why many studies older than the year 2000 were categorized into Group 3, when the search criteria were described in Section 5.1 to be restricted to those later than this cutoff date.

Stephen M. Roberts, Ph.D.

The search strategy used to identify key studies able to inform the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes is clearly described in the report. The search strategy to identify candidate papers, including search engines and search

ED_005043_00063236-00046

strings are listed, and the process of selecting the most useful studies through a three-step screening process is well described. The rationales for categorization decisions of specific papers is presented in tabular form which offers transparency to the analysis. The criteria for selection of the key studies is reasonable and scientifically appropriate.

Joanne F. Rovet, Ph.D.

This seems reasonable, although ultimately perhaps a bit too restrictive as some very good studies were eliminated from the final selection. A few critical references are missing (see above). Nevertheless, the quality of analysis was thorough, exhaustive, and very systematic. Unfortunately, most of the studies making the final cut were from Europe, particularly the Netherlands, which I believe has higher iodide sufficiency than the US.

DRAFT

ED_005043_00063236-00047

Question 9. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA conducted a three-step literature review, which identified 15 studies with information that could inform the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes.

Question 9B. Please also comment on the summary and characterization of the literature in Chapter 5 of the MCLG Approaches Report and identify any inaccuracies or mischaracterization of the studies.

Hugh A. Barton, Ph.D.

The descriptions of the literature were generally clear and application of the criteria for categorization appeared reasonable. Not having read the original literature, I cannot comment on the accuracy of these summaries. The section includes studies with findings of relationships between thyroid hormone levels and neurodevelopment and studies that do not find such relationships, or do not find relationships for some endpoints. It provides EPA's perspective on the overall database. In the document, EPA indicates that, based upon comments in previous peer reviews, they did not conduct a systematic review. EPA should consider whether a formal systematic review would strengthen their analysis.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

The summary and characterization of the literature in Chapter 5 appeared appropriate to me. However, I note that under column label "Effect Estimates" the note that "[β based on untransformed…]" suggests that beta coefficients are shown but odds ratios are sometimes shown (i.e. exponentiated betas). I suggest changing the note to "[Estimates based on untransformed…]". I note that indicating what estimates are shown (i.e. mean change in outcomes, odds ratios or other) would help clarify what is being shown.

Claude Emond, Ph.D.

No comment at this time.

Dale Hattis, Ph.D.

I have no difficulty and no suggestions for improvement of the document on these issues.

ED_005043_00063236-00048

Angela M. Leung, M.D., M.Sc.

The reference to T4 in the Oken 2009 study in Table 22 should be clarified as total T4. Other than this, along with the exception the Haddow 1999 study noted above, the summary and characterization of studies as listed in Tables 10-22 appear to be accurate.

Stephen M. Roberts, Ph.D.

Group 2 studies are summarized in tabular form in Chapter 5 and short narrative form in Appendix E; Group 1 studies are described in narrative form in Chapter 5, including tables with key data from these studies. The level of detail provided for both Group 1 and 2 studies is appropriate for the purposes of this report and I did not identify any inaccuracies or mischaracterizations.

Joanne F. Rovet, Ph.D.

This is quite well done and thorough. I was very impressed and appreciated seeing the data digitized for some of the studies. I also liked the evaluation (section 7.1) examining population shifts. I wonder too whether more might be said of the findings from studies that produced the opposite relations that were found and what these findings may be due to or mean.

DRAFT

ED_005043_00063236-00049

Question 10. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA focused on five studies that evaluated the relationship of maternal fT4 and several neurodevelopmental endpoints (IQ, MDI, PDI and reaction time) based on the measurement of fT4 during early pregnancy at weeks 12, 13 and 16.

Question 10A. Please comment on the assumptions, strengths and limitations of focusing on the five studies and associated neurodevelopmental end points to inform an MCLG, including but not limited to study design, evaluation of neurological endpoints, sample size, iodide nutrition status, potential confounders such as smoking, and study population.

Hugh A. Barton, Ph.D.

One concern is whether there would be a method to allow consideration of the findings of multiple studies, including those with negative findings (either overall or for specific measures, such as IQ or Bayley Scales MDI or PDI). There is mention of a couple of papers that provide meta-analysis, so there are a few studies that are sufficiently similar to be combined. It may be that evaluating the exposure-response using multiple studies is the best approach allowing some estimate of an average and variability.

Nancy Carrasco, M.D., M.S.

Again, although I am not an expert on these kinds of analyses, it seems to me that focusing on these five studies was appropriate and sound, even though it would have been better to have more than five studies, if they existed.

Jonathan Chevrier, Ph.D.

As mentioned above, selecting only studies that reported significant results is likely to overstate the relation between perchlorate and neurodevelopment. Assuming that results are unbiased and that each study sample was selected at random, results from each study represents a point on a distribution of possible results, centered on the true association. Because only one study could be selected for each outcome, it is unclear where published results lie on that distribution.

I think that it is important that EPA take into account the quality of the studies used as part of this exercise, but it is unclear to me whether this was done. A clear framework for the evaluation of such studies should be developed and applied. Some limitations include:

- Korevaar et al. controlled for instrumental variables (e.g. gestational week at fT4 measurement) as well as variables that are consequences of altered fT4 (e.g. maternal BMI), which may have biased estimates. This study also assumed a log-linear relation between fT4 and the outcome but it is unclear whether the data fit this functional form better than a linear form. Reanalysis of the data performed by EPA should not include the variables noted above, which may have driven measures of association towards the null, and should

ED_005043_00063236-00050

investigate the most appropriate functional form to inform decisions about transformation of fT4 values.

- Finken et al. also controlled for BMI in their fully-adjusted model and fit a regression over the entire range of fT4. They do not appear to have investigated functional forms other than a linear relation, although it would be reasonable to believe that fT4 may not affect child neurodevelopment over a certain (normal) range. Authors mention that they standardized fT4 values for the postmenstrual day at which sampling occurred but it is not clear how this was performed.

- Regression coefficients for the studies by Pop et al. were based on very small samples (n=22 and 57) and so it is unclear how reliable these coefficients are. Small studies are more likely to find extreme results and small studies with significant results are more likely to be published. In addition, my understanding is that the scatter plots that were used to derive regression coefficients were not adjusted for confounders. Finally, the predictive potential of Bayley scores at a young age (i.e. 6 months to 2 years) on neurodevelopment at older ages is unclear.

This said, studies by Korevaar et al. and Finken et al. have the advantage of having been conducted on relatively large samples and evaluated neurodevelopment in children aged 5-6 years. However, the fact that all of the studies measured fT4 via immunoassays, which can be biased by the concentration of T4-bound proteins, remains a notable limitation. The fact that no studies were conducted in a U.S. population is also a potential limitation.

Claude Emond, Ph.D.

No comment at this time.

Dale Hattis, Ph.D.

The covered studies are plenty to analyze the likely IQ response to perchlorate.

Angela M. Leung, M.D., M.Sc.

The report focuses on the results of five studies that demonstrate adverse neurocognitive effects of offspring of hypothyroxinemic women (based on serum FT4 concentrations as a continuous measure) during early pregnancy.

- **Study design**: Study designs were essentially identical, in which measurements of perchlorate, thyroid function, other analytes from banked maternal sera collected during early pregnancy were correlated to at least one measure of neurocognition in their offspring. In the absence of more prospective, adequately-powered studies (i.e., CATS trial), this is the only type of study design that can feasibly assess the longitudinal outcomes of interest many years later.

ED_005043_00063236-00051

- **Neurological endpoints**: This is commented briefly in Section 6.5.2 of the report. The neurocognitive outcomes among the offspring were measured at fairly disparate ages (range: 10 months to 10 years of age). The neurocognitive outcomes were also different and included IQ, reaction time, and psychomotor development. Although these are fairly reasonable differences, given the paucity of published data otherwise, it would be prudent to consult with a psychologist with expertise in childhood test measures and thyroidology to comment on these outcomes. As we know there is continuing development of different structural areas during postnatal neurogenesis (see Bernal J, PMID 17315033), further expertise is needed to correlate whether the adverse outcomes are reasonable with the timecourse of thyroid hormone-dependent neurogenesis.
- **Study size**: This is commented on briefly in Section 6.5.4 of the report. There was a wide variation in the sample sizes of the five included studies (number of mother-infant pairs): 22, 27, 57, 1765, and 3839. However, even though three of the studies were relatively small, significant associations between maternal hypothyroxinemia and adverse neurocognitive outcomes of interest were still observed. The report did not restrict studies based on small sample size alone.
- **Iodine status**: This is commented briefly in Section 6.5.3 of the report. Among the five studies, urinary iodine concentrations (as a marker of iodine status) were variably assessed. The Korevaar 2016 study (n=3839) assessed urinary iodine in a subset of 672 women and the Vermiglio 2004 study (n=27) measured urinary iodine in the full sample, but the remaining three studies did not at all. If urinary iodine concentrations are abnormally high or low (i.e. both directions outsides of the "adequate" range) in the datasets, adjustment for these values may reasonably alter the strength and/or directionality of the findings. However, as mentioned in question #5 above, there are limitations of using urinary iodine concentrations to interpret iodine status in a given individual. Iodine status is much more reliably measurable on the population level.
- **Potential confounders**: The number and type of potential confounders adjusted for in the five studies varied considerably, as is shown in the footnotes of Table 22.
- **Study population**: This is commented briefly in Section 6.5.1 of the report. The five studies were conducted mostly in The Netherlands (4 studies), and there was also one small study in Italy (Vermiglio 2004, n=27). Italy has historically been an iodine-deficient country, and although the Vermiglio study measured urinary iodine to categorize the 27 women into 16 who resided in an iodine-deficient region of the country vs 11 who resided in an iodine-sufficient region, the actual urinary iodine concentrations were not used, but rather they were categorical measures used in the analyses examining offspring IQ. The Netherlands has examined only pregnant women for population iodide status (www.ign.org), which in 2002-2006 was considered adequate. This information increases the reliability of the findings in the 4 studies arising from The Netherlands, in which only one measured and adjusted for urinary iodine in a small subset of the study sample.

Stephen M. Roberts, Ph.D.

The final selection of five studies was based principally on the availability of data in a form that could be used to describe the quantitative relationship between maternal fT4 and one or more endpoints related to neurodevelopment. Given the goal of including neurodevelopmental

ED_005043_00063236-00052

outcomes in a quantitative model, focusing on these studies is logical. Study designs were appropriate to provide the needed information. Smoking as a potential confounder was addressed in some but not all of the studies, and information on iodine nutritional status was available to varying extents among the studies. Limitations in information provided by these studies are discussed well in Section 6.5, and I am not aware of any additional limitations.

Joanne F. Rovet, Ph.D.

I sensed a naiveté in understanding the meaning of the endpoints and their relation to underlying brain function. Despite an excellent appendix describing the relevance of the two BSID versions for Dutch children, I sense some need for caution in interpreting these results. The Bayley scales are a measure of developmental appropriateness and how well the child has achieved the level relevant to peers, whereas Wechsler tests represent how well the child actually performs relative to population norms. Dutch children often score above American. It is interesting to note that the distribution of IQ scores for American children has a different shape and a different midpoint than for Canadian, hence a separate scoring system for the latter. All of these population differences should be understood when making predictions.

As for SDRT, this is an index often used to characterize children with attention disorders and doesn't represent intelligence. However, RT itself may be a gross proxy to intelligence. It is interesting to note too that effects of maternal hypothyroxinemia were mostly on non-verbal perceptual aspects of intelligence and not global IQ itself or verbal IQ. The nonverbal aspects of intelligence are usually subserved by more posterior brain regions that develop earlier than anterior and may receive their thyroid hormone via the choroid plexus.

DRAFT

ED_005043_00063236-00053

Question 10. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA focused on five studies that evaluated the relationship of maternal fT4 and several neurodevelopmental endpoints (IQ, MDI, PDI and reaction time) based on the measurement of fT4 during early pregnancy at weeks 12, 13 and 16.

Question 10B. Please comment on whether the chosen studies are sufficient in number, quality, and robustness for the purpose of informing the derivation of an MCLG.

Hugh A. Barton, Ph.D.

See comments on 10a.

Nancy Carrasco, M.D., M.S.

I think the studies chosen are sufficient for the purpose of informing the derivation of an MCLG, even though, as I indicated above, a larger number of studies, if available, would have been desirable.

Jonathan Chevrier, Ph.D.

It appears to me that the small number of studies linking fT4 with neurodevelopment and the lack of overlap between studies in terms of outcome are important limitations that will make it challenging to derive an MCLG.

Claude Emond, Ph.D.

The data available are enough in number, but may be eclectic when compared. The concept linking the reduction of fT4 to neurodevelopment is known; however, the variability between studies, particularly in regard of concentration measured, may require comparing the methodology used or refining the methodology. I think EPA did great, and more importantly the maximum amount with the information available from epidemiological studies.

Dale Hattis, Ph.D.

The covered studies are plenty to analyze the likely IQ response to perchlorate.

Angela M. Leung, M.D., M.Sc.

The remaining ten studies that also studied these and other neurodevelopmental endpoints, but which did not report significant associations, were not included for the purposes of a perchlorate MCLG derivation. Excluding these studies lessens the power of the total sample size and thus

ED_005043_00063236-00054

the ability to detect an association between maternal hypothyroxinemia and any of the offspring outcomes, but provides what may be a somewhat exaggerated estimate of the potential adverse effects of perchlorate exposure. This approach is more conservative, to which there are pros and cons of doing so, toward derivation of a perchlorate MCLG. With this approach, the goal is to minimize exposure to the lowest perchlorate concentration associated with any number of adverse outcomes.

I would favor the more liberal public health approach, which is inclusion of all available studies, whether they are positive or negative. Although the perchlorate MCLG may be higher, this latter approach would be consistent with using all available evidence to improve the scientific rigor of the proposed study question.

Stephen M. Roberts, Ph.D.

While one can always wish for more studies, more subjects, and more endpoints, the chosen studies are sufficient in number, quality, and robustness to inform the derivation of a MCLG.

Joanne F. Rovet, Ph.D.

I think this could have been improved by combining the results across the 5 studies using SD or Z-scores and the SD of RT scores (not SDRT) of the groups.

DRAFT

ED_005043_00063236-00055

Question 10. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA focused on five studies that evaluated the relationship of maternal fT4 and several neurodevelopmental endpoints (IQ, MDI, PDI and reaction time) based on the measurement of fT4 during early pregnancy at weeks 12, 13 and 16.

Question 10C. Please provide advice on reducing any identified limitations.

Hugh A. Barton, Ph.D.

See comments on 10a.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

Given the limitations that I noted above, should EPA decide to go ahead with this approach, I think that models should focus on the most robust studies, i.e. those of Korevaar et al. and Finken et al. but an attempt to integrate strong studies with negative results must be made. The re-analysis of the Korevaar et al. data may be the best avenue given that Finken analyzed data over the entire range and ignored potential nonlinearities. This analysis should not include gestational age at the time of fT4 measurement or BMI as confounders. If measurement error due to variation in gestational age when fT4 was measured is of concern, these values should be corrected to represent values at the same stage (e.g. based on a model relating gestational age and fT4). Also, a model stronger than the linear regression used by EPA would be based on a smoother which would avoid assuming a linear relation and reduce the influence of outliers or other particularly influential points on the prediction. EPA may want to consider asking Finken et al.'s data to re-analyze data over the lower range of fT4 and/or using smoothers without controlling for BMI.

Claude Emond, Ph.D.

No comment at this time.

Dale Hattis, Ph.D.

The covered studies are plenty to analyze the likely IQ response to perchlorate.

ED_005043_00063236-00056

Angela M. Leung, M.D., M.Sc.

It may be interesting to compare the model outputs if the remaining ten studies in Group 1 (that did not report a significant association between maternal hypothyroxinemia and at least one offspring neurocognitive measure) were included vs. not included in the further analyses.

Stephen M. Roberts, Ph.D.

I have no advice on reducing limitations, but as stated in response to the previous question, consider the studies adequate for the purpose of informing derivation of a MCLG.

Joanne F. Rovet, Ph.D.

I would have liked more discussion on other thyroid disruptors.

DRAFT

ED_005043_00063236-00057

Question 11. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA used regression analyses to predict the magnitude of change in each of the neurodevelopmental endpoints given a change in fT4 as a result of increased perchlorate exposure at different iodide intakes.

Question 11A. Please comment on the assumptions, strengths, and limitations of using the regression analyses to inform the relationship between thyroid hormone levels and neurodevelopmental outcomes. Please also comment on the various functional forms of the regression equations (e.g. linear, log-linear, quadratic) in each of the relationships.

Hugh A. Barton, Ph.D.

Using regression analysis to describe exposure-response appears reasonable. It does not appear appropriate to try to apply some form of PKPD modeling to analyze these results.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

As I noted below, the fact that different functional forms were assumed by different studies presents some challenges. First, the distributional form of independent variables should not influence decisions to transform them, as they have little effects on the distribution of residuals in least square (linear) regression. Functional form should either be based on known "exposure"-response relationships or on examination of the data and determination of the form that fits the data best.

Although a quadratic form fit the data by Korevaar et al. well over the entire range of fT4 (and the fact that this relation makes biological sense), I support EPA's suggestion to focus on data at the lower range of fT4 to develop their prediction model. As noted above, I would suggest that EPA not force any functional form on the data but simply apply a smoother. This will avoid the question of the range of fT4 values over which the model should be run and potentially different results that could be obtained depending on the range selected

Claude Emond, Ph.D.

The analysis of data, using different regression equations, is not unusual.

ED_005043_00063236-00058

Dale Hattis, Ph.D.

As indicated earlier, I believe the regression analyses can and should be improved by substituting Michaelis-Menten transforms for the log(perchlorate) levels in the analyses. See the response to question #3 above.

Angela M. Leung, M.D., M.Sc.

The use of multivariable linear regression would appear to be an appropriate statistical analysis based on the available data, but I defer to the other reviewers with modeling expertise. I have reviewed the summary data presented in Tables 38 and 39, but am unable to comment further on the various functional forms of the regression equations.

Stephen M. Roberts, Ph.D.

The regression analysis is a logical approach to quantifying the relationship between maternal fT4 and various neurodevelopmental deficits. There are a number of limitations and uncertainties associated with this approach that are candidly summarized in Section 6.5.6, including the uncertainties associated with the form of the regression equations. I agree with these limitations and have no additional limitations to add.

Joanne F. Rovet, Ph.D.

This is fine but maybe the meaning of the numbers could be better explained for those less familiar with this approach. Also, the p-values should be given or identified consistently. I think the text could better explain the contents of the table.

DRAFT

ED_005043_00063236-00059

Question 11. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA used regression analyses to predict the magnitude of change in each of the neurodevelopmental endpoints given a change in fT4 as a result of increased perchlorate exposure at different iodide intakes.

Question 11B. Please identify additional data or analyses EPA could use to quantify the relationship between thyroid hormone levels and neurodevelopmental effects, including how this information would be expected to improve the analysis.

Hugh A. Barton, Ph.D.

None identified.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

See responses above.

Claude Emond, Ph.D.

No further comment.

Dale Hattis, Ph.D.

The use of a Michalis-Menten formulation as indicated in (a) above and in the response to question 3 will provide a more biologically plausible relationship to fit. Because it carries an extra parameter (Km) it will also likely lead to a better fit to the empirical data although a full analysis will need to adjust for this in judging whether the fit is improved enough to justify the added complexity of the model.

Angela M. Leung, M.D., M.Sc.

There are some scant data regarding structural brain size differences in offspring born to hypothyroid women by Dr. Rovet's group, but the classifications of exposure do not appear to have been based on maternal serum FT4 concentrations. There may be additional data regarding morphological brain differences among offspring using maternal FT4 in the future.

ED_005043_00063236-00060

Stephen M. Roberts, Ph.D.

I am not aware of any additional data or analyses that could be used to quantify the relationship between thyroid hormone levels and neurodevelopmental effects.

Joanne F. Rovet, Ph.D.

The use of cut-points might be included. The categorical approach needs better explaining.

DRAFT

ED_005043_00063236-00061

Question 11. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA used regression analyses to predict the magnitude of change in each of the neurodevelopmental endpoints given a change in fT4 as a result of increased perchlorate exposure at different iodide intakes.

Question 11C. Please comment on whether there is a magnitude of change in fT4 below which the relationship between fT4 and neurodevelopmental effects should not be used because it is too uncertain.

Hugh A. Barton, Ph.D.

No comment.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

A change that is smaller than the level of precision of instruments used to measure fT4 would not be reliable. Changes that can otherwise be detected by instruments are of interest.

Claude Emond, Ph.D.

There are 2 things here. First, I agree that the magnitude reported is uncertain; however, it provides a level of change associated with doses. It should indicate the confidence we have with the value.

Dale Hattis, Ph.D.

I believe there is no such lower limit to the applicability of the analysis.

Angela M. Leung, M.D., M.Sc.

This is commented on briefly in Section 6.5.6 and Table 34 of the report. The reasoning provided, that worse neurodevelopmental outcomes would be biologically plausible and expected with even lower maternal serum FT4 concentrations, is reasonable, and I would not think there would be a specific FT4 cutoff corresponding to a loss of effect.

ED_005043_00063236-00062

Stephen M. Roberts, Ph.D.

I have not yet formed an opinion on this question and look forward to discussion with other panel members during the face-to-face meeting in formulating my response.

Joanne F. Rovet, Ph.D.

I didn't understand why the 50th percentile values were used.

DRAFT

ED_005043_00063236-00063

Question 11. Identification of Published Literature and Quantitative Relationship of Thyroid Hormone Levels to Neurodevelopmental Outcomes. EPA used regression analyses to predict the magnitude of change in each of the neurodevelopmental endpoints given a change in fT4 as a result of increased perchlorate exposure at different iodide intakes.

Question 11D. Please comment on whether other studies that were identified in the literature search (e.g., studies that found categorical relationships between fT4 and neurodevelopmental outcomes, studies that found effects but lacked statistical significance, studies that did not find an effect) could be utilized to quantitatively characterize the relationship between fT4 and neurodevelopmental outcomes or inform uncertainty associated with the analysis presented.

Hugh A. Barton, Ph.D.

It does not seem feasible to develop an exposure response from the categorical findings, but they can be used, as done by EPA, to evaluate qualitatively whether there is consistency between categorical and continuous analyses.

Nancy Carrasco, M.D., M.S.

No comment.

Jonathan Chevrier, Ph.D.

I think that it is important to consider studies that found results that were not statistically significant, especially if sample size is of reasonable size and risk of bias is low. I recommend EPA focus on effect size rather than statistical significance. Studies of good quality that found no effect also have value as they can help estimate the true population values if multiple studies with similar outcomes can be combined. Ideally, multiple studies would be combined in an overall estimate in a meta-analysis together with a confidence interval and this value would be used to predict the impact of perchlorate, but too few studies can be combined in this case.

Claude Emond, Ph.D.

I am not aware to any other study, published or not.

Dale Hattis, Ph.D.

My literature search did not identify additional helpful studies.

ED_005043_00063236-00064

Angela M. Leung, M.D., M.Sc.

Please also see my comments to Questions #10b and 10c. The literature search produced ten studies (that assessed maternal serum FT4 concentrations as a continuous measure which did not observe an adverse effect on offspring neurocognition), as well as those in Group 2 that assessed serum FT4 as categorical measures. Although their inclusion may not necessarily be recommended in the final model, comparison of the estimated effects on the various neurocognitive outcomes with and without these may indeed inform the degree of uncertainty inherent in the present model. Several of the studies in Group 2 were able to demonstrate significant adverse outcomes (Berbel 2009 as one excellent example), and also their more global nature would help support the generalizability of the present model.

Stephen M. Roberts, Ph.D.

Data from studies that found no effect or effects that lacked statistical significance could in theory contribute to a quantitative characterization of the relationship between fT4 and neurodevelopmental outcomes, but the approach would need to be considered carefully. As the report points out, the absence of an effect (or a significant effect) in some studies may be due to range of fT4 considered. Combining studies that are dissimilar in critical ways would confound rather than improve the derivation of a quantitative maternal fT4-neurodevelopment outcomes relationship. Studies finding categorical relationships can be used to inform uncertainty with the analysis presented.

Joanne F. Rovet, Ph.D.

Certainly, the CATS study needs to be included. I think the list otherwise was quite complete, but I would have liked more discussion or further highlighting of the Craig study, given it is American and from a very reputable group. I would have liked more discussion on behavioral outcomes, beyond cognitive, such as ADHD and autism and their increased incidence in the population. Author(s) need to include the work of S. Anderson of Denmark on fetal programming of later mental illness and how perchlorate might contribute to this.

DRAFT

ED_005043_00063236-00065

Question 12. Alternative Population-Based Approach and Comparison to the Two-Stage Approach Linking Thyroid Hormone Levels to Neurodevelopmental Outcomes. Please comment on the assumptions, strengths and limitations associated with the population-based approach that is focused on a shift in the proportion of the population that could be considered hypothyroxinemic.

Hugh A. Barton, Ph.D.

This is an appropriate approach for consideration. However, it has the disadvantage of appearing to be focused on potentially transient changes in thyroid hormone levels that one could debate whether the effects are adverse. For the two-stage approach, the end point is clearly adverse; that is, neurodevelopmental deficits in offspring of women who had low thyroid hormone levels. There may be a significant risk communication advantage to having a clearly adverse endpoint as the basis for the MCLG analysis rather than changes in thyroid hormone proportions in the population.

Nancy Carrasco, M.D., M.S.

This topic is outside my area of expertise. I am unable to provide any comments on it.

Jonathan Chevrier, Ph.D.

I believe that this approach has value. Hypothyroxinemia has the potential to impact numerous systems and health outcomes and focusing only on neurodevelopment has the disadvantage of ignoring other health effects of hyothyroxinemia.

Claude Emond, Ph.D.

No comment.

Dale Hattis, Ph.D.

I think the precise definition of "hypothyroxemic" has nothing to do with the real effects of perchlorate on offspring IQ and other relevant parameters of effect. The only relevance is how the medical community reacts with "cases" of "hypothyroxemia" in terms of treatment.

Angela M. Leung, M.D., M.Sc.

This is a reasonable approach to provide a perhaps rough estimate of the magnitude of the impact of perchlorate on a population level, but assumes that there must be an allowable proportion of the population in which maternal hypothyroxinemia associated with potential later adverse outcomes is acceptable. This is in line with some public health perspectives, in which

ED_005043_00063236-00066

interventions are implemented to benefit the vast majority (but not all) of those at risk in a given population.

As the report describes in detail (Section 7.2), there are also many assumptions and uncertainties toward deriving this estimate, including but not limited to the definition of maternal hypothyroxinemia during pregnancy; the limitation of the analyses to gestation weeks 12/13/16 since neurogenesis begins as early as gestational week 3; and the choice of what constitutes an allowable hypothyroxinemic proportion of the population.

With both approaches, there are still issues surrounding the definition of adequate iodine status as noted previously (Question #5); the response of TSH to varying degrees of low iodine, low FT4 levels, and perchlorate (separately and additively); and uncertainties regarding duration of perchlorate exposure.

Stephen M. Roberts, Ph.D.

The population-based approach relies upon BBDR modeling to predict the relationship between perchlorate dose and fT4, and thus has all of the strengths and limitations associated with that modeling in common with the two-stage approach. It avoids, however, additional uncertainties associated with extending the model to predict neurodevelopmental outcomes, relying instead on the premise that increasing the percentage of the population of pregnant women that is hypothyroxinemic increases the number of fetuses at risk. A population-based approach also simplifies somewhat estimates of the number of people that might benefit from management of perchlorate in drinking water to specific concentrations. Also, it is supported directly by studies showing, through categorical analysis, a relationship between hypothyroxinemia and increased risk of adverse neurodevelopmental effects. A limitation in this approach is that the explicit endpoint (a decrease in fT4 levels) is not an adverse effect per se, but is instead a precursor effect in a specific population. It is not a scientific limitation, but rather a communication challenge when explaining the approach to some audiences.

Joanne F. Rovet, Ph.D.

I like this approach. I think increasing the population frequency of hypothyroxinemia is a relevant outcome to assess following perchlorate exposure in pregnancy.

On cardiovascular disease, might there be a comparable effect in the offspring, that should be studied.

ED_005043_00063236-00067

Question 13. Alternative Population-Based Approach and Comparison to the Two-Stage Approach Linking Thyroid Hormone Levels to Neurodevelopmental Outcomes. Hypothyroxinemia is the condition of having an abnormally low level of T4 in the blood and TSH is in the normal range, and in diagnosing this condition the threshold for "abnormally low" is often selected to be the 2.5th, 5th or 10th percentile of the population fT4 distribution. Because the BBDR model can be calibrated to any given percentile, but does not predict the distribution of fT4 levels, it was necessary to derive a fT4 distribution to identify a hypothyroxinemic threshold. EPA assumed a lognormal distribution with a Geometric Standard Deviation based on 2 to 3 studies depending on the gestational week. There is uncertainty regarding the true fT4 levels at various percentiles in the distribution around the median output from the BBDR model. For example, some of the analyses show larger unit changes with increasing percentiles of fT4 in most analyses (See tables 24, 30, 31, 32, 33 and Section 6.5.6 of the MCLG Approaches Report). Please comment on the assumptions, strengths and limitations of the derived fT4 distribution for the purposes of this analysis.

Hugh A. Barton, Ph.D.

No comments, as this is outside the reviewer's area of expertise.

Nancy Carrasco, M.D., M.S.

This topic is outside my area of expertise. I am unable to provide any comments on it.

Jonathan Chevrier, Ph.D.

The fact that the model predicts stronger effects at higher levels of fT4 is a major limitation that gives me pause in the use of the model with its current specifications because it makes little biological sense. This may be due to the fact that fT4 was assumed to be log-normally distributed, which does not agree with my own experience. I think that EPA should evaluate the impact of this choice of a distribution and revert to a normal distribution if models generate results that agree better with our understanding of the biology – i.e. that effects of perchlorate on child neurodevelopment should be stronger among women with low fT4 to begin with. One way or another the discrepancy between the model's results and current knowledge must be reconciled.

Claude Emond, Ph.D.

The strategy used by the EPA was probably the best, considering the availability of the information. It is usually not appropriate to juxtapose different studies, but here it gives us at least a range of information.

ED_005043_00063236-00068

Dale Hattis, Ph.D.

I have already commented in some detail on the expected interindividual variability in fT4 levels. See my response to question 7c.

Angela M. Leung, M.D., M.Sc.

The 2.5th, 5th, and 10th percentiles have been the conventional choices in defining a maternal serum FT4 concentration for defining hypothyroxinemia during pregnancy. Section 6.5.6 of the report describes the uncertainties surrounding the selection of a specific cutoff. Negro et al. (PMID 21247845) has also recently reviewed this topic. The current report has selected a 10th percentile FT4 cutoff, and thus presents what may be a relatively higher proportion of women with hypothyroxinemia compared to the lower cutpoints (i.e. the American Thyroid Association defines the condition as the lowest 2.5th or 5th percentile of a given population). I defer to the other reviewers regarding the model code of the derived FT4 distribution.

Stephen M. Roberts, Ph.D.

I have not yet formed an opinion on this question and look forward to discussion with other panel members during the face-to-face meeting in formulating my response.

Joanne F. Rovet, Ph.D.

My only comment is whether the 10th percentile is too high to be considered "hypothyroxinemia", in the sense of being a clinical condition.

DRAFT

ED_005043_00063236-00069

Question 14. Alternative Population-Based Approach and Comparison to the Two-Stage Approach Linking Thyroid Hormone Levels to Neurodevelopmental Outcomes. Please comment on the strengths and limitations of the two-stage approach versus the alternative population-based approach to inform the derivation of an MCLG.

Hugh A. Barton, Ph.D.

Both approaches are attractive. It is difficult to compare the strengths and limitations of the two methods, as the probabilistic analysis involves many technical elements this reviewer cannot evaluate. While population approaches are desirable, and often model reviewers are uncomfortable when only an average result is presented, it is also frequently true that there is greater uncertainty involved in adequately describing population variability as compared to the population average behavior.

As noted in response to question 12, there may be a significant risk communication advantage to having a clearly adverse endpoint as the basis for the MCLG analysis rather than changes in thyroid hormone proportions in the population.

Nancy Carrasco, M.D., M.S.

This topic is outside my area of expertise. I am unable to provide any comments on it.

Jonathan Chevrier, Ph.D.

The population-based approach certainly has the advantage of relying on fewer assumptions, but it is not clear what threshold should be used to define hypothyroxinemia. The two-stage approach has the advantage of predicting health effects, but the number of studies to derive estimates is small and it is unclear how the negative studies can be integrated in this framework.

A limitation of both methods is that they do not appear to consider the uncertainty of the BBDR model. Estimates are simply taken as is and, in the case of the two-stage model, applied to the confidence intervals of the studies of fT4 and neurodevelopment.

Claude Emond, Ph.D.

No comment.

Dale Hattis, Ph.D.

The MCLG is mostly a policy position. There are, as far as I can see, no real thresholds in the relationships described.

ED_005043_00063236-00070

Angela M. Leung, M.D., M.Sc.

Both approaches have their advantages and disadvantages. The two-stage approach is inherently based on more granular individual data, albeit from only a few large datasets drawn primarily from The Netherlands, to estimate discretely decreased maternal serum FT4 levels following perchlorate exposure to result in later adverse offspring neurocognitive outcomes, and thus in theory offers a more stringent estimate of the risks of perchlorate exposure. The alternative population-based approach uses a conventional public health perspective to estimate an allowable proportion of pregnant women to be at potential risk for the adverse offspring effects in order to potentially implement an intervention to decrease risks for the vast majority, but not all, of those who may develop the adverse outcome.

Stephen M. Roberts, Ph.D.

The two-stage approach is consistent with the vision of the 2013 SAB, which uses a model capable of predicting quantitatively neurobehavioral outcomes in relation to perchlorate exposure. Although additional refinements in the model are possible, especially as new information becomes available, all of the component pieces are in place. The model is informed by, and calibrated to the extent possible using, human data, which is a considerable strength. The alternative population-based approach has many of the same strengths as the two-stage approach, but stops short of quantifying neurobehavioral outcomes based upon perchlorate effects on thyroid hormone levels. The strengths and weaknesses of this approach are discussed in the response to Question 12.

Joanne F. Rovet, Ph.D.

I am not sure what is meant by the alternative.

DRAFT

ED_005043_00063236-00071

Question 15. <u>Alternative Population-Based Approach and Comparison to the Two-Stage Approach Linking Thyroid Hormone Levels to Neurodevelopmental Outcomes</u>. EPA has developed a two-stage approach linking the revised BBDR model results with quantitative information on neurodevelopmental outcomes from epidemiological studies. Please comment on the utility of the this two-stage approach for predicting potential impact of perchlorate exposure in early pregnancy on neurodevelopmental outcomes in the population at varying levels of iodide intake. Please comment on whether there are better strategies for estimating the potential impact of perchlorate exposure in early pregnancy on neurodevelopmental outcomes that are likely to be more scientifically defensible than the approaches presented (e.g. Appendix C estimates IQ impact directly from perchlorate exposure using Steinmaus et al. and Korevaar et al., or potentially some alternative studies). If an alternative approach would be more appropriate, please outline specifically how the approach might be developed given the current available state-of-the-science and data.

Hugh A. Barton, Ph.D.

Given the limitations of the data, the two approaches considered seem stronger than using the results of a single study to relate perchlorate exposure directly to neurodevelopmental outcomes.

Nancy Carrasco, M.D., M.S.

This topic is outside my area of expertise. I am unable to provide any comments on it.

Jonathan Chevrier, Ph.D.

I commend EPA for engaging in such a complex enterprise. In my opinion, this approach would have greater value if a larger number of studies were available that allowed for the computation of a summary estimate. Although evidence for an impact of maternal fT4 during early pregnancy on child neurodevelopment is convincing, there remains much uncertainty regarding the precise association (in terms of strength and functional form) between these variables. Although apparently not quantified, there is also uncertainty associated with the BBDR model.

The limitations that I mentioned above also apply to the approach presented in Appendix C and so would not help in determining which approach is best. I also note that in this approach log-linear relations were assumed for both models, but I am not sure whether another function fit the data better and, here again, smoothers could avoid questions about functional form. In addition, I am not clear why, if epidemiological studies are to be used to derive an MCLG, research investigating relations between prenatal exposure to perchlorate and child neurodevelopment were not used. Attempting to combine results from different studies conducted in different populations certainly adds to the uncertainty and potential for bias.

This said, whether the two-stage or the method presented in Appendix C is based on the confidence that one puts into the BBDR model relative to epidemiological studies, I think that the method from Appendix C could have some value if a large number of studies was meta-analyzed. However, in this particular case only one study was used to evaluate each relation

ED_005043_00063236-00072

which is insufficient to predict effects with any reasonable level of certainty. I would thus favor the two-stage approach.

Claude Emond, Ph.D.

No comment.

Dale Hattis, Ph.D.

I think use of the Steinmaus and Korevaar data is the best approach that can be done at present.

Angela M. Leung, M.D., M.Sc.

The use of the two-stage approach, linking the current model to quantitative data from available studies, is reasonable for predicting the population impact of environmental perchlorate exposure. Although the quantitative data are relatively few in number and from primarily a single country, and thus could be improved to add power and generalizability, they do represent probably what is currently known about this evolving topic. Future studies that specifically examine the perchlorate content of banked biospecimens collected during early pregnancy and correlated with offspring neurodevelopmental outcomes would offer more direct and confirmatory evidence of these relationships. Furthermore, animal models may offer additional mechanistic insight of perhaps independent effects of perchlorate on neurogenesis apart from decreasing maternal thyroid hormone levels.

Stephen M. Roberts, Ph.D.

Alternative approaches such as the examples in Appendix C would not be more appropriate than using BBDR modeling. Based upon current understanding of thyroid physiology and the MOA for perchlorate, susceptibility to development of adverse neurodevelopmental outcomes from perchlorate exposure is complex and can be influenced by a variety of factors (e.g., iodide intake, co-exposure to other goitrogens, gestational age). BBDR modeling allows these factors to be addressed explicitly and quantitatively in establishing a safe exposure level for perchlorate. Through modeling, a variety of subpopulations and exposure scenarios of interest can be evaluated. This is more scientifically defensible than basing a MCLG on observations from a single study such as the Steinmaus et al. example in Appendix C. Aside from limitations of this specific study (lack of concurrent timing of measurements of perchlorate exposure and fT4, estimation of perchlorate exposure from a single spot urine sample, measurement of fT4 in the second rather than first trimester, and others), whenever a single study is used there is uncertainty whether the study population adequately represents other populations of interest/concern.

ED_005043_00063236-00073

Joanne F. Rovet, Ph.D.

I like this approach and consider it to be state-of-the-art in relation to what is currently available. It represents a significant improvement over the previous modelling approach.

V. SPECIFIC OBSERVATIONS ON REPORT (VOLUME 1)

Hugh A. Barton, Ph.D.

Specific Observations on Report (Volume 1) - *Hugh A. Barton, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
2-2	2	The point of this paragraph is unclear.
2-5	2 of 2.4	Did NRC consider inhibition of iodide uptake nonadverse no matter how much inhibition or were they saying that low percentage inhibition would be nonadverse? Or, is that not clear?
3-5	Sec 3.2	Merrill et al. 2005 missing from reference list
5-18	Table 12	What does N/A stand for?

Nancy Carrasco, M.D., M.S.

Specific Observations on Report (Volume 1) - *Nancy Carrasco, M.D., M.S.*		
Page	**Paragraph**	**Comment or Question**
1-2	4	"However, it must be noted that, because the adult euthyroid human thyroid contains several months of T4 stored in the colloid,.." The claim that the human thyroid stores several months' worth of T4 is a very significant one, yet no reference is provided. Also, a more precise time frame should be given.
8-1	3	"It must be noted that, because the adult euthyroid human thyroid contains several months of T4 stored in the colloid, ..." Here too, there is no reference.
3-13	1	"This likely occurs because the half-life of (organified) iodine in the adult thyroid is around six months." Once again, no reference is given.
1-1	4	"Ingestion exposures are of concern because perchlorate is easily and almost completely absorbed from the gastrointestinal tract (Srinivasan & Viraraghavan, 2009)." In this case, the reference given is a review, and once I located the relevant text in the review, I discovered that there was no reference to a primary research article.
2-7	3	"There is evidence from cell culture work that perchlorate is actively transported into the thyroid gland and this transport may be enhanced by increasing TSH and reduced in a dose-dependent manner by iodide (Tran et al., 2008). This active transport is potentially due to the upregulation of NIS (Hussein, Abbas, El Wakil, Elsamanoudy, & El Aziz, 2012)."

ED_005043_00063236-00075

Specific Observations on Report (Volume 1) - *Nancy Carrasco, M.D., M.S.*		
Page	**Paragraph**	**Comment or Question**
		This text is somewhat misleading. The evidence that perchlorate is actively transported into the thyroid gland is not limited to results from cell culture work. There is in vivo evidence published in 1959 (Anbar et al.) from the thyroid glands of rabbits and rats, and data showing NIS-mediated perchlorate transport into the milk in rat dams [Dohán et al., (2009) PNAS]. It is puzzling that the latter reference was not included. The authors use a systems biology approach to quantitate the inhibition of NIS-mediated I- transport at different concentrations of perchlorate.
3-3	1	"In particular, a decrease in fT4 is predicted to increase blood TSH, the response to which is an increase in the thyroid NIS activity and production rate constants for T4 and T3." This statement is not accurate. The direct response to an increase in TSH is higher NIS expression: TSH does not directly stimulate NIS activity. NIS activity increases only as a result of higher NIS expression
3-4	1	"Partitioning of perchlorate into red blood cells and binding to plasma protein are included in this model, unlike that of Lumen et al. (2013)." What is the evidence that perchlorate partitions into red blood cells? The plasma membrane is not permeable to perchlorate, which is an anion. Thus, NIS is required for perchlorate to be translocated across the plasma membrane, and NIS is not expressed in erythrocytes. Also, what is the evidence that perchlorate binds to plasma proteins?
3-5	2	"The Vmax for NIS-mediated uptake is also increased during pregnancy based on independent data." It is not clear what the evidence for this claim is, as no reference is given. What are the independent data mentioned?
3-5	2	"The perchlorate sub-model is analogous to that of the iodide model and describes the assumed mechanism of action for perchlorate. That is, once perchlorate is consumed it is distributed throughout the body, including to the thyroid plasma, where it can bind to NIS, which inhibits the uptake of iodide." This statement is inaccurate. Perchlorate does not "distribute to the thyroid plasma, where it can bind to NIS, which inhibits the uptake of iodide." Rather, perchlorate binds to an anion binding site on NIS, after which NIS translocates the perchlorate into the cytosol, thus preventing iodide from binding to NIS and being translocated into the cell.

ED_005043_00063236-00076

Specific Observations on Report (Volume 1) - *Nancy Carrasco, M.D., M.S.*		
Page	**Paragraph**	**Comment or Question**
2-4	2	"Conditions of low maternal iodine may also cause fetal thyroid function to be impacted once it begins, thereby putting the fetus at risk of developing hypothyroxinemia due to the lack of iodine coming from the mother to create its own thyroid hormone." This statement should be reworded for clarity: Low maternal iodine may also impair thyroid function once it begins, thereby putting the fetus at risk of developing hypothyroxinemia because it does not have enough iodine with which to synthesize its own thyroid hormone(s).
3-5	Table 1	"..that is adjusted for NIS-mediated uptake in skin and mammary glands" What is the evidence that there is NIS-mediated I- uptake in the skin? And regarding the mammary gland, NIS-mediated I- transport has been reported in the lactating mammary gland only, not in the non-lactating mammary gland. This point needs to be made clear.
3-11	Figure 5	How long did the perchlorate exposure last that yielded the data shown in Figure 5?
3-15	4	"The higher PC for perchlorate (80% increase in perchlorate ROB coefficient) reflects the higher ratio of Vmax/Km for NIS-mediated transport into mammary and skin for perchlorate versus iodide. The BBDR model assumes this type of distributional impact of NIS uptake is plausible; however, it has not been evaluated using empirical data." Contrary to what this statement suggests, the NIS Vmax and Km for perchlorate have actually been determined experimentally (Dohán et al., PNAS).
3-16	2	"Al-Rasheed et al. (2015) identified several variations in the DNA sequence characterizing the NIS gene as a potential variable influencing the development of differentiated thyroid cancer. While these data are not directly informative within the context of perchlorate, it demonstrates that variability in the NIS gene structure exists and may plausibly represent an important factor rendering individuals more or less sensitive to perchlorate exposure." This statement is misleading and inaccurate. The results presented in the paper cited do not indicate that individuals may be more or less sensitive to perchlorate exposure. This is a candidate gene study conducted in a very small cohort. Studies of this type, including this one, were carried out 10 years ago without population stratification or multiple testing correction. More

ED_005043_00063236-00077

Specific Observations on Report (Volume 1) - *Nancy Carrasco, M.D., M.S.*		
Page	**Paragraph**	**Comment or Question**
		importantly, of the 5 SNPs, only one is in an exon, and it is a silent mutation, as the codon still codes for cysteine. Three SNPs are in introns and the last SNP is in the 3' UTR (untranslated region). Therefore, none of the SNPs has any impact or effect on the NIS amino acid sequence or on NIS activity.
3-17	1	"The association between perchlorate and diminished T4 in the face of elevated TSH (Steinmaus, et al., 2013; Steinmaus, et al., 2007; Blount et al. 2005) suggests that certain segments of the population (low iodide, smokers) respond more weakly than others." The interpretation of the report cited is not correct. The findings presented in this paper do not suggest variability in certain segments of the population. From the way that the molecular mechanism of NIS functions, it follows that when people have low plasma iodide concentrations, there will be more pronounced inhibition by perchlorate. The effect observed in smokers is due to the high concentrations of thiocyanate that smokers have in their plasma. Like perchlorate, thiocyanate is a NIS inhibitor and a NIS substrate.
3-18	2	"Because it assumes euthyroid status, it does not, for example, address thyroiditis, which is caused by the production of thyroid autoantibodies (e.g., Hashimoto's Disease) and is a relatively common condition that may involve impaired iodide uptake across the NIS and in some individuals, may result in reduced production of T4." This statement is incorrect. Hashimoto's disease is the most common (not a relatively common) cause of hypothyroidism in the US. Therefore, it is not surprising that patients with Hashimoto's disease have lower levels of thyroid hormones.
3-18	2	"Brent (2010) raises the possibility that perchlorate and similar environmental exposures could increase the risk for Hashimoto's Disease." It is not clear why this statement was included in the report. The Brent paper cited does not even mention Hashimoto's disease.
3-5	2	"This inhibition (of NIS by perchlorate) reduces the thyroid's stores of organified iodide, and hence decreases the rate of formation and release of T3 and T4. As fT4 levels decline, the predicted concentration of TSH increases, thereby stimulating iodide uptake and thyroid hormone production, allowing for a partial compensation for the inhibition: the resulting decline in fT4 is less than it would be in the absence of this mechanism."

ED_005043_00063236-00078

Specific Observations on Report (Volume 1) - *Nancy Carrasco, M.D., M.S.*		
Page	**Paragraph**	**Comment or Question**
		This statement is conceptually incorrect, because it mistakenly assumes that a rise in TSH will result in increased iodide uptake and thyroid hormone production even in the continuous presence of perchlorate. What actually happens is that, as long as perchlorate is present, even a higher number of NIS molecules at the plasma membrane will not transport more iodide; instead, they will continue to transport more perchlorate, and there will be no compensation whatsoever for the inhibition. Moreover, nowhere in the report is it explicitly stated that perchlorate inhibits NIS-mediated iodide transport because perchlorate itself is translocated by NIS as a substrate. Mechanistically and pathophysiologically, there is a very important difference between an inhibitor being a blocker and an inhibitor being a substrate. Perchlorate is actively transported by NIS; this means that when perchlorate is present, it will be accumulated in all the tissues where NIS is expressed, including the thyroid, salivary glands, and stomach—and, critically, the lactating breast. In other words, if a mother who is breastfeeding is exposed to water contaminated with high concentrations of perchlorate, she will produce lower levels of thyroid hormones, and her newborn will receive perchlorate in the maternal milk in addition to receiving less iodide. This twofold harm will cause the newborn to synthesize thyroid hormones at lower levels at precisely the stage of life at which (s)he is most sensitive to inadequate thyroid hormone levels, given that thyroid hormones play a crucial role in the development and maturation of the central nervous system postnatally.

Jonathan Chevrier, Ph.D.

Specific Observations on Report (Volume 1) - *Jonathan Chevrier, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
2-2	2	The last sentence of this paragraph appears to suggest that higher total T4 will result in lower TSH. Is this correct? This would suggest that bound T4 can be detected by thyroid receptors in the pituitary gland and hypothalamus. I suggest that the sentence be re-phrased. The description of this phenomenon in section 2.2 (page 2-3 to 2-4) is more accurate. It is also unclear why this information is repeated in contiguous paragraphs.
2-5	1	The main effect of thyroid peroxidase (TPO) with regards to hypothyroidism and TPO antibodies is to catalyze 1) the iodination of tyrosine residues and 2) the coupling of iodotyrosine residues in thyroglobulin to form T4 and T3. The conversion of T4 to T3 is primarily handled by iodinases, I would also recommend using a textbook reference rather than a web page

ED_005043_00063236-00079

Specific Observations on Report (Volume 1) - *Jonathan Chevrier, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
		developed for the general public (which is improperly cited in the reference list). Webner and Ignmars' The Thyroid may work for that. Another option is Ruf J and Carayon P (2006) Arch Biochem Biophys; 445(2): 269-277.
3-2	2, last sentence	This sentence appears to be important but was confusing to me. Does this sentence mean that only exposure levels causing fT4 blood concentrations to be reduced at levels that would not be anticipated to trigger an increase in TSH were considered? If so, it appears to me that a better justification for this decision is warranted.
Throughout document		The terms iodine and iodide appear to be used alternatively throughout the document, which can be confusing/distracting. This sometimes happens in the same paragraph, for instance, the last complete sentence of page 3-9 and the sentence beginning on the last line of that same page.
4-2	1	It is not entirely clear to me how GSDs were back-calculated. The use of an Excel function is not necessary. Values simply need to be logged, an SD of the logged values calculated and then the SD to be exponentiated using the base of the log used for the initial transformation to compute the GSD. Essentially do I understand that 1) data were log-transformed and SDs were calculated, 2) these values were averaged across study populations, and 3) the average values were exponentiated using the base of the log used in step 1? I think this needs to be clarified. This brings another important concern. The standard deviation of combined populations is not equal to the (weighted) average of their standard deviations. The proper formula is: $$\sum_{j=1}^{n}(\overline{x_j}-\bar{x})^2 = \sqrt{\frac{\sum_{i=1}^{g} n_i\sigma_i^2 + \sum_{i=1}^{g} n_i(\overline{x_i}-\bar{x})^2}{\sum_{i=1}^{g} n_i}}$$ Where g is the number of populations, n_i is the sample size of population i, $x(bar)_i$ is the mean for population i, σ_i is the standard deviation for population i, and x(bar) is the overall average. This would need to be calculated on logged values and then exponentiated. Also, do I understand that data from the Mannisto study were included twice to calculate the 12-13 week GSD values? The fact that these data are not independent needs to be considered in computing these statistics.

ED_005043_00063236-00080

Specific Observations on Report (Volume 1) - *Jonathan Chevrier, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
		In addition, combining these populations requires strong assumptions, i.e. that there is a single population with overall GM and GSD from which each study was sampled. Is this a correct assumption? My understanding is that the distribution of thyroid hormone is population-specific. If that is the case, is it appropriate to combine data from different populations? The fact that no data from a US population is available should be noted as a limitation. Finally, was log-normal distribution expected for fT4? My own experience is that fT4 is consistently normally distributed. One thing to keep in mind is that immunoassays were used by all studies to measure fT4. Several studies have shown that immunoassays could be biased by the concentration of T4-bound proteins and that physical separation by equilibrium dialysis or ultrafiltration were gold standards to measure fT4. Could this or other factors explain such a skewed distribution of fT4? Also, the use of immunoassays to measure fT4 in the studies used should be considered a limitation.
4-2	Last	Last sentence: I don't understand how GSDs can be used to represent medians.
4-3	1	I did not understand this paragraph. I do not see why a separate GSD needs to be calculated for the low-iodine group and why standard deviations are compared between the 2.5th and 50th percentiles vs 50th and 97.5th percentiles. Certainly, reducing the GSD at lower levels of iodine intake would result in less extreme estimates of fT4 and, presumably, weaker effects of perchlorate than would otherwise be estimated by keeping the GSD constant. I also do not understand how the fT4 distributions were computed for different perchlorate exposure levels.
4-4	Table 6	Is the exposure level or the internal dose of perchlorate represented here?
4-6	1	I think that it is important to mention the consequences of assuming a log-normal distribution over a normal distribution. Presumably, the impact of perchlorate will be estimated to be smaller in the low fT4 concentrations when using a log-normal distribution, which could have important implications for the ultimate objective of this exercise (estimate the impact of perchlorate on lowering fT4 and subsequent effects on child neurodevelopment). I think that more thought needs to be given to the choice of fT4 distribution and its impact on results by conducting sensitivity analysis by running the models assuming a

ED_005043_00063236-00081

Specific Observations on Report (Volume 1) - *Jonathan Chevrier, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
		normal distribution of fT4. As I mentioned previously, the fact that a log-normal distribution may describe some published results raises concerns about the validity of the results given what is generally reported in terms of distribution.
5-2	Table 9	I was surprised that "thyroid" or "thyroid hormone" were not part of the search terms. I am also surprised that for some outcomes both T4 and thyroxine were used and for others, only thyroxine was used. I can't think of a reasonable rationale for this inconsistency. Also, restricting some search strings to the title may have resulted in missed articles (and using a different strategy for different strings is highly unusual). Although Google Search can list very large numbers of articles, PubMed generally generates a more reasonable number of hits when bollean terms are used (e.g. neurodevelopment AND hypothyroxinemia yielded 45 hits)
5-3	Last	I can see little justification for using only studies that found significant results between fT4 and neurodevelopment. Studies finding no significant results also have values if valid methods were used. Using only significant studies could overestimate the effect of perchlorate on fT4. If EPA believes that this method should be kept, the fact that the model may overestimate perchlorate's toxicity should be acknowledged.
5-4	Last bullet point	Small studies with significant results are generally believed to be more prone to publication bias – this is in fact what is evaluated when using funnel plot to estimate publication bias. Again, by eliminating studies with non-significant results and including small studies with significant results, the model's results may be affected by publication bias and overstate relationships. Also, was any information collected about the quality of the studies including potential for selection, information and/or confounding biases? Studies of poor quality (high risk of bias) should not be considered.
6-3	1	In the following sentence the units for fT4 should be indicated so that the coefficient can be understood.
6-4	Table 24	It is not clear how the confidence intervals were derived for these estimates. Was the uncertainty in deriving changes in fT4 due to perchlorate and changes in the outcome due to changes in fT4 considered? It seems to me that both of these should be reflected in the uncertainty of the prediction. Also, it makes little sense to me that the effect of perchlorate on reaction time would be stronger at the median of fT4 than at the 2.5th percentile. Would this be due to the assumed log-normal distribution of fT4?

ED_005043_00063236-00082

Specific Observations on Report (Volume 1) - *Jonathan Chevrier, Ph.D.*		
Page	**Paragraph**	**Comment or Question**
6-6	Whole page	Here a linear regression was fit on the data representing the lower 50 percent of fT4. Essentially, EPA has decided that values in the higher percentile of fT4 should not influence the shape of the association in the lower 50 percent. EPA could have gone further by fitting a spline on the data, thereby neither forcing a quadratic relation over the range of fT4 but also not forcing a straight line below the 50th percentile of fT4. This method would also reduce the influence of outliers or other influential points on the beta coefficient (slope). Also, a note should indicate whether standard regression assumptions were verified (including the linearity assumption and evaluating the impact of influential points). In addition, I note that gestational age at blood sampling for fT4 measurement is not a confounder. This variable is not a causal determinant of IQ and thus, although a determinant of fT4, does not qualify as a confounder (such variables are termed instrumental variables). Also, BMI is a variable that is affected by thyroid hormones and as such not only does it not qualify as a confounder but could be a mediator of the fT4-IQ relation. Controlling for such a variable instrumental variables and mediators is considered to be over-control and can bias estimates of associations (most likely towards the null). Proper control for confounding could affect estimates in Table 26 and (properly) drive them away from the null and generate significant results for the multivariable model. Finally, the distribution of fT4 will not determine whether residuals from the linear regression are normally distributed (only the distribution of the outcome will). Therefore, the fact that fT4 was not normally distributed is no reason to log-transform this variable. Log-transforming fT4 assumes that the relation between fT4 and IQ is log-linear (i.e. multiplicative). Is there any reason to believe this? Does this function fit the data better than a linear-linear relation? Answers to these questions are important to ensure that predictions for changes in IQ are accurate and since EPA has the data on hand, they are able to answer them. I also note that the Pop et al. and Vermiglio et al. studies assumed linear-linear relations with the PDI, which is inconsistent.
6-11	Table 30	Here again, I find it difficult to explain that effects of perchlorate on IQ would be stronger at the median and 10th percentile of fT4 than at the 2.5th percentile. Stronger effects should occur at lower fT4 levels and so results suggest problems with the model.

Angela M. Leung, M.D., M.Sc.

Specific Observations on Report (Volume 1) - *Angela M. Leung, M.D., M.Sc.*		
Page	**Paragraph**	**Comment or Question**
18	Footnote 2	Suggest inserting the word **serum** before each mention of FT4 and TSH, i.e. "serum FT4 values" and "serum TSH"
20	2	This should read: "TSH acts on the thyroid gland to stimulate **iodine uptake to result in decreased** thyroid hormone production."
21	2	Suggest that the text regarding suppressed TSH be separated in order to clarify that this does not result from increased serum TBG concentrations. The text would be clearer as follows: "For example, as the first trimester progresses, increases in beta human chorionic gonadotropin (beta-hCG)[4], estrogen, and thyroid binding protein result in a higher serum T4 concentrations, making more fT4 available to the developing fetus (Morreale de Escobar, Obregón, & del Rey, 2007). Serum TSH concentrations are also mildly suppressed due to the action of beta-hCG as a mild thyroid hormone stimulator."
22	1	It is unclear what the two processes are from the ensuing text following this sentence: "In the first trimester of pregnancy, this increased output of thyroid hormones is due to **two specific processes**."
23	2	The word "because" is repeated twice. Suggest: "Maternal fT4 is particularly important in the first trimester of pregnancy because the fetal brain is solely dependent upon T4 of maternal origin during this period (Zoeller & Rovet, 2004), **as** the fetal thyroid gland does not form and become mature until later in development."
23	3	It is unclear what time period this sentence refers to. I think the text is meant to read and should be changed to the following: "Historically, the most commonly observed thyroid conditions resulting from hypothyroidism **in pregnancy** have been goiter (i.e., enlarged thyroid gland) and congenital hypothyroidism."
23	3	Technically, the list refers to hypothyroidism rather than hypothyroxinemia, since the latter is relevant only during pregnancy. Suggest: "**Hypothyroidism** may result from iodine

ED_005043_00063236-00084

Specific Observations on Report (Volume 1) - *Angela M. Leung, M.D., M.Sc.*		
Page	**Paragraph**	**Comment or Question**
		insufficiency, genetic disorders, autoimmune thyroid disease, thyroid surgery, pituitary insufficiency, or environmental factors."
23	4	**Hashimoto's thyroiditis** does not necessarily cause subclinical hypothyroidism, but rather increases the risk of hypothyroidism, whether it be subclinical or overt hypothyroidism. (i.e. There is a difference between Hashimoto's thyroiditis and hypothyroidism resulting from Hashimoto's thyroiditis.) Suggest: "Hashimoto's disease increases the risk of hypothyroidism, including both subclinical and overt hypothyroidism. Subclinical hypothyroidism is defined by only elevated TSH concentrations, yet serum T3 and T4 concentrations remain within the population reference range, while overt hypothyroidism is defined by elevated serum TSH concentrations concurrent with decreased serum T3 and T4 concentrations."
23	4	The term "clinical hypothyroidism" is confusing and not a conventional medical diagnosis. Suggest: "Subclinical hypothyroidism has the potential to progress to **overt hypothyroidism over time**, thus requires serum thyroid function test monitoring."
24	2	Suggest: "However, since the 2005 NRC report was published, several epidemiological studies have shown perchlorate exposure to be associated with changes in serum thyroid hormone levels (Blount et al., 2006; Steinmaus et al., 2013; Steinmaus et al., 2016) and Taylor et al. (2014), as well as an association between high maternal perchlorate exposure and risk of low IQ in offspring (Taylor et al. 2014)."
24	3	I think this should be hypothyroidism instead of hypothyroxinemia, as they are not interchangeable. Suggest: "Given the importance of a properly functioning thyroid for fetal and child growth (Forhead & Fowden, 2014), **hypothyroidism** may also be associated with abnormal fetal and child growth."
25	Figure 3	Now that hypothyroxinemia pathway has been added, the hypothyroidism box can be confusing. Hypothyroidism in the black box is meant to denote a situation of increased serum TSH and decreased serum T4/T3 concentrations (i.e. both must be met), whereas the blue hypothyroxinemia box denotes a situation of isolated serum T4 concentrations (technically this does not include T3) in the setting of **normal** serum TSH concentrations. Thus, suggest clarifying with subnotes in each of the hypothyroxinemia and hypothyroidism boxes to indicate the direction of serum T4/T3, T4, and TSH concentrations.
26	1	The word "overt" would clarify the intent of this sentence. Suggest: "Even without the presence of perchlorate as a thyroid disruptor, it is likely that the population is already exposed to a range of thyroid-affecting substances that may result in **overt** hypothyroidism

ED_005043_00063236-00085

Specific Observations on Report (Volume 1) - *Angela M. Leung, M.D., M.Sc.*		
Page	**Paragraph**	**Comment or Question**
		(elevated TSH, low fT4), subclinical hypothyroidism (elevated TSH, normal fT4), or hypothyroxinemia (normal TSH, low fT4) that will effectively be worsened by exposure to further endocrine disruption caused by perchlorate."
27	2	Consider inserting text to clarify that perchlorate has an approximate 30-fold relative higher potency than iodide to be taken up by thyroidal NIS. PMID 15650353.
28	1	Serum TBG concentrations approximately double (rather than decrease) during the first trimester and remain elevated until the end of gestation, thus this sentence appears to be incorrect. "…increases in hCG result in a higher production of T4 and reduced TSH **and TBG** (Morreale de Escobar et al., 2007)."
32	Figure 4	Suggest either "urine" or "urinary excretion" to maintain consistency throughout.
56	3	Regarding the "Iodine intake data for the study population" bullet, it would also be informative to know the number of subjects the urinary iodine measurements were obtained in. A study sample of >125 individuals is considered reliable when interpreting population urine iodine concentrations measured from a spot urine sample. Small study samples may not be accurate to form conclusions for population iodine status. The size of the study population is addressed in a later bullet, but for different reasons.
95	Table 2	It would be easier to read the table if it was split into the 5 studies for which further analysis was performed for the MCLG derivation and the 10 studies that were not further analyzed.
134	2	Presents an alternative population-based…
140	2	In addition, **subclinical hypothyroidism** (when the serum TSH is elevated but serum T3 and T4 levels remain normal) has been similarly associated with other cardiovascular risk factors, including diastolic hypertension, weight gain, insulin resistance, as well as congestive heart failure and mortality. A brief discussion can be inserted regarding this, which is different from hypothyroidism (inferred as overt hypothyroidism) reviewed in this section. Here are some references regarding adverse cardiovascular outcomes associated with subclinical hypothyroidism: 1. Andersen MN, Olsen AM, Madsen JC, et al. Subject: Materials needed

Peter,
As a follow up from Mike's general with Sarah yesterday, she would like a background paper on perchlorate. I'm hoping that you have something already prepared that I can provide to her. I'm also copying Christine in case she has something already available.

Subject: FW: FOR REVIEW: draft perchlorate response to comment document
Attachments: Consolidated Perchlorate Draft Comment Response Document 5-19-20 v2.docx

Crystal and Lisa;
Jennifer spoke with me today about her comments on the perchlorate response to comment document. She has reviewed the Chapters 1-7 and is in the midst of reviewing Chapter 8. She stated that the responses in Chapters 1-7 are well written.
She is concerned that Chapter 8 contains some redundant responses in which the same issues are addressed. She asked that someone review chapter 8 responses with an eye toward reducing redundant responses and assuring that we don't have inconsistent language contained where we do have redundant responses. Crystal since you were able to do that effectively for Lead Free, I would like your help in doing that in Chapter 8 of the attached document.

Please note that

1. Jennifer is continuing with her review and will forward the document to Charlotte B with the understanding we can make combine changes that Crystal makes with any changes that result from Jennifer and Charlotte's review.
2. Jennifer prefers the Lead Free approach to summary responses for each section. She does not want us to change what we have done for perchlorate but when we prepare the LCR response to comment document she wants it to look more like the Lead Free document than the perchlorate document.

Good Morning,

There's some confusion in OW over our submittal of the perchlorate docs. for Charlotte's review. Joe asked that I enter the attached documents into CMS (w/o review) for Charlotte. Is this the formal submittal? To initiate OMB Review, we need to follow the Action Development Process checklist (as applicable) and label the FRN per the attached guidance. (Note: submit the FAR memo and associated concurrences in on PDF file.)

Thanks for your timely attention...any questions, please let me know, thanks!

Yvonne; Please see the draft note to Mike about perchlorate peer review. Also please find attached a draft one pager for the A.O. describing our activities. Please note the attached is still under review by OGC but I am sending to you and copying Dawn so that she can convey and comments/concerns to all once she has had a chance to review.

Mike:
Please find attached, a one page summary of our activities on perchlorate. The attached provides background information, identifies key issues and a timeline for moving forward. The attached highlights the recently completed peer review of the biologically based dose response (BBDR) model for perchlorate and the planned peer review of methodologies to develop alternative MCLGs using the BBDR model.

Please note that we recently received the final peer review report for the BBDR model. We plan to post this peer review document to our docket so that the public will be able to view the recommendations we have received for how to improve the BBDR model. The peer reviewers identified a number of areas for improvement or modification of the existing model for predicting thyroid hormone level changes caused by perchlorate exposure. The peer

reviewers recommended that the Agency develop a plan for further actions in order to maximize the benefit of any model revisions that are undertaken and to make decisions about priorities, timelines, and resources. Peer reviewers noted that models can always be improved, but the goal is to have a model that is fit for the intended purpose. The peer reviewers noted that the lack of a clear definition of that purpose for this model (i.e., how the model outputs would be used in developing the desired drinking water regulations) contributed to the difficulty they had in assessing whether the model was sufficiently good to apply.

We are working with our colleagues in ORD and FDA to implement many of the recommendations the peer reviewers made to the BBDR model. We believe that the purpose of the BBDR model will be more evident with the preparation of the MCLG Report that will describe alternative approaches for applying the BBDR model to develop potential perchlorate MCLGs. We hope to brief the Administrator's office on the perchlorate peer review process in April and intend to cover the recommendations from the first peer review and the draft MCLG report in April.

Please let us know if there is any more information you would like us to prepare in order inform the Administrator's office of these important activities.

Eric,
Jennifer and I do not recall teeing up (at the bi-weekly or LCR meetings) the Perchlorate peer review report and placing it in the docket to Mike. Do you or Lisa remember doing so? Anything Please advise. I don't want to hold anything up on the comms side, but I also know Ann is going to ask if we did.

DESK STATEMENT

To ensure the safety of drinking water for all Americans, EPA is continuing the regulatory process for perchlorate in drinking water. In response to recommendations from our Science Advisory Board, the agency is developing two new analyses to inform selection of a health based goal (the Maximum Contaminant Level Goal or MCLG) for the regulation. The first new analysis is the development of a biologically based dose response (BBDR) model and the second analysis is the development of methodologies to derive a MCLG for the regulation using the BBDR model. The agency held a peer review of the first of two new analyses to ensure the agency's perchlorate regulatory decision-making is based on the best available science. EPA has received the peer review report, is reviewing the recommendations and will be taking actions to improve the BBDR model as appropriate. EPA plans to conduct a second peer review of the second analyses describes methodologies for deriving a MCLG for using the BBDR model. To find a copy of the report please visit:
https://www.epa.gov/dwstandardsregulations/perchlorate-drinking-water

Action Information

Action Title: National Primary Drinking Water Regulation for Perchlorate, Tier 1, SAN 2040-AF28, significant

Purpose: To improve the health protection to drinking water consumers from perchlorate.

Background: On February 11, 2011, EPA announced its decision to regulate perchlorate based on its finding that perchlorate meets the SDWA's three criteria for regulating a contaminant. SDWA requires that EPA propose a drinking water regulation within 24 months of a determination to regulate a contaminant (February, 2013) and finalize the regulations 18 months after proposal (can extend up to 9 months).

Stakeholder Involvement: EPA consulted with the National Drinking Water Advisory Council in 2012 on potential requirements of the perchlorate regulation. EPA has also met or corresponded with industry groups including the Perchlorate Study Group, American Chemistry Council, the American Water Works Association and the U.S. Chamber of Commerce. EPA was sued by the Natural Resources Defense Council in 2016 for the Agency's failure to issue proposed and final regulations for perchlorate in accordance with SDWA timelines.

Key Issues/Internal Review: The key issue for perchlorate is establishing the Maximum Contaminant Level Goal (MCLG[1]) which is defined in SDWA as the "level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety." In early 2012, the Agency sought recommendations from EPA's Science Advisory Board on how to derive a MCLG for perchlorate in accordance with SDWA. The SAB recommended that EPA derive a perchlorate MCLG that addresses sensitive life stages through physiologically-based modeling. In response to SAB recommendations, FDA and EPA scientists worked to develop models to relate perchlorate exposure to biological effects to infants and other life stages. EPA completed an expert peer review of the models, and we are preparing for a second expert peer review of methodologies to apply the model to identify potential MCLGs for perchlorate. Once peer review of these analyses are completed, OW will brief the Administrator and seek input on at what level the MCLG should be set and whether the Agency should

Ex. 5 Attorney Client (AC)

Legal Deadlines: EPA is under a consent decree with enforceable dates of October 31, 2018 for signature of a proposed MCLG and NPDWR and a signature date of December 19, 2019 for the final MCLG and NPDWR for perchlorate.

Timing: In order to complete necessary analyses for development of a proposed rule, including the Heath Risk Reduction Cost Analysis required by SDWA, we will need to initiate expert peer review of the approaches to derive an MCLG in mid May and complete the review in October 2017. We would like to brief the A.O. about peer review in April.

---

[1] Maximum Contaminant Level Goal (MCLG) is a non-enforceable public health goal. The enforceable standard, the Maximum Contaminant Level (MCL) is set as close to the MCLG as feasible using best available treatment technology and taking cost into consideration.

Purpose: To improve the health protection to drinking water consumers from perchlorate.

Background: On February 11, 2011, EPA announced its decision to regulate perchlorate based on its finding that perchlorate meets the SDWA's three criteria for regulating a contaminant. SDWA requires that EPA propose a drinking water regulation within 24 months of a determination to regulate a contaminant (February, 2013) and finalize the regulations 18 months after proposal (can extend up to 9 months).

Stakeholder Involvement: EPA consulted with the National Drinking Water Advisory Council in 2012 on potential requirements of the perchlorate regulation. EPA has also met or corresponded with industry groups including the Perchlorate Study Group, American Chemistry Council, the American Water Works Association and the U.S. Chamber of Commerce. EPA was sued by Natural Resource Defense Council in 2016 for the Agency's failure to issue proposed and final regulation for perchlorate in accordance with SDWA timelines.

Key Issues/Internal Review: The key issue for perchlorate is establishing the Maximum Contaminant Level Goal (MCLG[1]) which is defined in SDWA as the "level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety." In early 2012, EPA sought recommendations from the Science Advisory Board on how to derive a MCLG for perchlorate in accordance with SDWA. The SAB recommended that EPA "derive a perchlorate MCLG that addresses sensitive life stages through physiologically-based pharmacokinetic/pharmacodynamic modeling." In response to SAB recommendations, FDA and EPA scientists worked to develop models to relate perchlorate exposure to biological effects to infants, and other life stages. EPA completed an expert peer review of the models, and we are preparing for a another expert peer review of methodologies to apply the model to identify potential MCLGs for perchlorate. Once peer review of these analyses are completed OW will brief the Administrator and seek input on what level the MCLG should be set and

Ex. 5 Attorney Client (AC)

Legal Deadlines: EPA is under a consent decree with a enforceable dates of October 31, 2018 for signature of a proposed action and a signature date of December 19, 209 for the finale action.

Timing: In order to complete necessary analyses for development of a proposed rule, including the Heath Risk Reduction Cost Analysis required by SDWA, we will need to initiate expert peer review of the approaches to derive an MCLG in mid May and complete the review in October 2017. We would like to brief the A.O. about peer review in April.

---

[1] Maximum Contaminant Level Goal (MCLG) is a non-enforceable public health goal. The enforceable standard, the Maximum Contaminant Level (MCL) The MCL is set as close to the MCLG as feasible taking cost into consideration.

Jennifer:

Attached for transmission to OW are revised versions of the FRN for the Perchlorate Final Action. There is both a clean and track changes version that includes edits made since initiating FAR (including the edits you asked for on Saturday and adding 3 more SAB recommendations to page 14 that were in the proposal but were not included in the draft we provided you on Friday). Also please find clean version of the transmittal memo from you to Dave Ross and the Action memo incorporating your edits.

Please note that there is also a redline version of the Action Memo for you to see the responses to your comments on the document. I do not recommend transmitting that memo to OW.

1. Change the title please. This was requested by OGC at Sr. Leadership levels.
2. Provide the same level of detail on the SAB recommendations as was included in the proposal.
3. I don't think the HRRCA text is necessary and do not want to add it at this stage since there are OGC edits that already make this clear.

Hi Eric,

Here is a revised Redline of the document (from FAR). We had a few questions/issues for your consideration about the attached file. Specifically:,

1- Page #1, Notice Tittle: We did not accept the edits to the notice tittle. Because, the tittle of the notice was specifically crafted by OGC to capture the multiple actions EPA is taking. Suggest consulting with OGC before modifying this tittle.
2- Page #14, SAB Recommendations: SAB provided 4 main recommendations in 2013 but we only listed the first recommendation. Please advise if we should list all 4 recommendations here or not.
3- Page #26, Missing HRRCA Text: This language was offered by TAB in its 5-13-20 version of the draft FRN, but it did not show up in the version provided by OGWDW with Eric's & Jennifer's comments. We have inserted the language here for the reviewer's consideration. Please advise if we should keep it.

Once you provide your feedback, I will modify the redline version and also provide a Clean copy for transmittal.

Thanks
Sam

Jennifer

Attached for your approval and transmittal to the Office of Water for their approval and transmittal to the Office Policy for initiation of interagency review is a *Federal Register* notice titled: "Notice of Final Action on Perchlorate." Also attached for your review are a draft transmittal memo from you to the Assistant Administrator of Water, a draft Action Memorandum and a track changes version of the FR notice that denotes the changes made as a result of Final Agency Review.

On February 11, 2011, the EPA published a determination to regulate perchlorate in drinking water (76 FR 7762). On June 26, 2019 (84 FR 30524), the EPA published the proposed National Primary Drinking Water Regulation for Perchlorate and requested public comments on multiple alternative actions, including withdrawing the 2011 determination to regulate perchlorate. The EPA received approximately 1,500 comments on the proposed rule. In the attached notice, the EPA is withdrawing the 2011 Regulatory

Determination and is making a final determination not to regulate perchlorate based on the Agency's consideration of public comments and the best available information.

I recommend that you approve and transmit the attached notice to the Office of Water for their review, approval and transmission to the Office of Policy to initiate interagency review in accordance with Executive Order 12866. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

Afternoon,

Please find an updated roll out. We can start the notifications asap.

**

RELEASE SCHEDULE
October 6, 2017

- SRMD informally notifies requestors via phone call (Eric)
- OGC notifies NRDC (via phone call) (Dawn)
- OGWDW/SRMD notification of Regional Contacts (Christina/Lisa)
- SRMD notification of federal partners (FDA, ATSDR, NIEHS, OMB)
- OPA notification of Regional PADS and federal agencies' (OW comms)

Release Day (when publically available on FR site; public inspection day)

8:00 a.m	OGWDW stakeholder heads up (Peter/Jennifer emails)
10:00 a.m	OCIR Congressional heads up emails (Matt)
11:00 p.m	Website goes live (Russ/Christina)
	Broader congressional notifications (emails with link to website) (OW Comms)

**** Send formal notification letters to requestors once available**

Jennifer:

Attached for transmission to OW are revised versions of the FRN for the Perchlorate Final Action. There is both a clean and track changes version that includes edits made since initiating FAR (including the edits you asked for on Saturday and adding 3 more SAB recommendations to page 14 that were in the proposal but were not included in the draft we provided you on Friday). Also please find clean version of the transmittal memo from you to Dave Ross and the Action memo incorporating your edits.

Please note that there is also a redline version of the Action Memo for you to see the responses to your comments on the document. I do not recommend transmitting that memo to OW.

Subject: RE: Notice of Final Action on Perchlorate

Hi Eric,

Attached are the revised Redline and Clean versions of the Perchlorate FR Notice. Once we are ready for OP's submittal to OMB let me know and I will provide a version that adheres to OP's file name formatting guidelines.

Thanks
Sam

Sam

1. Change the title please. This was requested by OGC at Sr. Leadership levels.
2. Provide the same level of detail on the SAB recommendations as was included in the proposal.
3. I don't think the HRRCA text is necessary and do not want to add it at this stage since there are OGC edits that already make this clear.

Subject: RE: Notice of Final Action on Perchlorate

Hi Eric,

Here is a revised Redline of the document (from FAR). We had a few questions/issues for your consideration about the attached file. Specifically:,

1- Page #1, Notice Tittle: We did not accept the edits to the notice tittle. Because, the tittle of the notice was specifically crafted by OGC to capture the multiple actions EPA is taking. Suggest consulting with OGC before modifying this tittle.
2- Page #14, SAB Recommendations: SAB provided 4 main recommendations in 2013 but we only listed the first recommendation. Please advise if we should list all 4 recommendations here or not.
3- Page #26, Missing HRRCA Text: This language was offered by TAB in its 5-13-20 version of the draft FRN, but it did not show up in the version provided by OGWDW with Eric's & Jennifer's comments. We have inserted the language here for the reviewer's consideration. Please advise if we should keep it.

Once you provide your feedback, I will modify the redline version and also provide a Clean copy for transmittal.

Thanks
Sam

Subject: Notice of Final Action on Perchlorate

Jennifer

Attached for your approval and transmittal to the Office of Water for their approval and transmittal to the Office Policy for initiation of interagency review is a *Federal Register* notice titled: "Notice of Final Action on Perchlorate." Also attached for your review are a draft transmittal memo from you to the Assistant Administrator of Water, a draft Action Memorandum and a track changes version of the FR notice that denotes the changes made as a result of Final Agency Review.

On February 11, 2011, the EPA published a determination to regulate perchlorate in drinking water (76 FR 7762). On June 26, 2019 (84 FR 30524), the EPA published the proposed National Primary Drinking Water Regulation for Perchlorate and requested public comments on multiple alternative actions, including withdrawing the 2011 determination to regulate perchlorate. The EPA received approximately 1,500 comments on the proposed rule. In the attached notice, the EPA is withdrawing the 2011 Regulatory Determination and is making a final determination not to regulate perchlorate based on the Agency's consideration of public comments and the best available information.

I recommend that you approve and transmit the attached notice to the Office of Water for their review, approval and transmission to the Office of Policy to initiate interagency review in accordance with Executive Order 12866. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

Jennifer:
Attached please find a revised Perchlorate Briefing documents. We had submitted a previous versions of these document for OW review along with the Perchlorate Reductions and Recommendations Documents. We have updated these documents while awaiting further comments from OW. The revisions made to the documents are as follows

- The one pager – Decision for Perchlorate Final Regulatory Action – Has been updated in response to Dave's request to incorporate information about the timing of the release of the stipulation to NRDC regarding the consent decree. This document reflects OGC's input.
- The Reductions Document – has been updated to reflect the information we received from the States of Maryland and Ohio regarding the status of the system that previously detected perchlorate at levels greater than 18ppb. We have also added a document number.
- The Recommendations Document has been updated to reflect add a Document Number.

If OW has not yet reviewed the last versions provided we recommend sending these forward to replace the versions awaiting review. If there are comments on the previous versions we can incorporate those prior to sending them forward.

Hi Jennifer,

A few edits from Dave. Please review and confirm. In particular, please address the comment bubbles in the "Perchlorate Reductions" document. Please also review the write-up under #4 in the "Perchlorate Recommendations for PWS" document to confirm that it uses guidance type language, rather than authoritative, regulatory language. Due to formatting, yellow highlights (rather than redline) show changed text.

This is due tomorrow by noon, so please let me know as soon as the edits are incorporated.

Thank you,
Janita

Jennifer

Attached for your approval and transmittal to the Office of Water for their approval and transmittal to the Office Policy for initiation of interagency review is a *Federal Register* notice titled: "Notice of Final Action on Perchlorate." Also attached for your review are a draft transmittal memo from you to the Assistant Administrator of Water, a draft Action Memorandum and a track changes version of the FR notice that denotes the changes made as a result of Final Agency Review.

On February 11, 2011, the EPA published a determination to regulate perchlorate in drinking water (76 FR 7762). On June 26, 2019 (84 FR 30524), the EPA published the proposed National Primary Drinking Water Regulation for Perchlorate and requested public comments on multiple alternative actions, including withdrawing the 2011 determination to regulate perchlorate. The EPA received approximately 1,500 comments on the proposed rule. In the attached notice, the EPA is withdrawing the 2011 Regulatory Determination and is making a final determination not to regulate perchlorate based on the Agency's consideration of public comments and the best available information.

I recommend that you approve and transmit the attached notice to the Office of Water for their review, approval and transmission to the Office of Policy to initiate interagency review in accordance with Executive Order 12866. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

<Christ.Lisa@epa.gov>
Subject: FW: Revised Document

Jennifer: Attached please find clean copies of the recommendations and reductions documents for perchlorate. We have incorporated your edits. Please note with respect to your question about CCR reporting of perchlorate monitoring

CCR regulations under 141.153.(d)(1) requires the CCR include data on detected contaminants subject to mandatory monitoring including

i. Contaminants subject to an MCL, action level, MRDL or TT
ii. Contaminants for which monitoring is required under the UCMR
iii. Disinfection byproducts or micriobial contaminants for which monitoring is required.

Therefore if a system monitors for perchlorate outside of UCMR there is no requirement to report it on the CCR. If a system monitored for perchlorate in the UCMR 1 and detected it, then they were required to report it on the CCR for the next 5 years because 141.153(d)(3)(ii) UCMR results "need only be included in CCR for 5 years from the date of last sample or until any of the contaminants becomes regulated and subject to routine monitoring requirements, whichever comes first."
ASDWA is making arrangements for us to speak with the impacted States on Friday and or Monday morning.

Thank you Eric & Lisa – The attached contain a very few edits/comments. And then, these are ready to go to OW for review. Regarding the outreach plan, continue to pursue the discussions with ASDWA and AWWA as we discussed and agreed to with Dave. However, I'm not sure that we can say these reports will be released soon, maybe it is better to say that there is the potential for them to be issued in the near term.

Thanks much,
Jennifer

Hi Lisa,

We got new information from the MD system. There was some misunderstanding with the information request but here is the latest.

The treatment plant at chapel hill was recently taken off line and it was replaced with new productions wells and treatment plant which started operations in January 27, 2020. Please see the new language that I have incorporated in the revised document below.

"EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that the Chapel Hill WFP was taken off line and it was replaced with a new treatment plant and five new production wells. The new treatment plant started operations on January 27, 2020. System personnel also indicated that monitoring was conducted in November 2019 and the analysis shows that perchlorate was not detected in either the source well water or the finished water."

Thanks
Sam

Thanks Sam.
Do we know exactly what the contractor asked each PWS? Based on this response: **EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that no follow-up/updated monitoring data for perchlorate is available.** It appears we only asked about monitoring…did the contractor ask about any changes in source water and/or treatment too?

Thanks,
Lisa

Pre-Publication Outreach for Reductions of Perchlorate in Drinking Water: Status February 2020

To confirm and/or update the information on the 15 water systems that detected perchlorate > 18 ppb during UCMR1, TAB staff will coordinate with ASDWA and AWWA.

Working with Alan Roberson of ASDWA, TAB staff will conduct calls with the states of Florida, Georgia, Louisiana, Maryland, Mississippi, New Mexico, Nevada, Ohio, Oklahoma, Pennsylvania, Puerto Rico and Texas to:

- Provide notification that we will be highlighting publicly available data from UCMR1 in a perchlorate occurrence status report to be released soon.
- Share the information on water system's in their state we have obtained and check to see if there's additional information to add (monitoring, source water change, treatment installed, etc).

Working with Steve Via of AWWA, TAB staff will:

- Provide notification that we will be highlighting publicly available data from UCMR1 in a perchlorate occurrence status report to be released soon.
- Share the information on member water system's we have obtained and check to see if there's additional information to add(monitoring, source water change, treatment installed, etc).

Schedule:

Contact ASDWA and AWWA – February 24

Schedule calls with States – February 25

Complete calls & obtain AWWA data – February 26-27

Update document – February 28

Subject: FW: Draft Perchlorate Response to Comment Document

Hi Eric,
Please see the attached draft response to comment document for the perchlorate proposal. There are comment bubbles in this version, but you can review in "no markup" if you'd prefer. I've also attached a key I used as a cross reference comments since some responses point to others. This is in my short had so may not be as useful for you. Let us know if you have questions or concerns.
Lisa

Subject: Draft Perchlorate Response to Comment Document

Hi Lisa,

Attached is the draft Perchlorate RtC Document. I incorporated the final input provided by ORD. This version also includes annotated comments from reviewers. Let me know if we should also provide a clean copy for review at this stage.

Thanks
Sam

Hi Lisa,

We got new information from the MD system. There was some misunderstanding with the information request but here is the latest.

The treatment plant at chapel hill was recently taken off line and it was replaced with new productions wells and treatment plant which started operations in January 27, 2020. Please see the new language that I have incorporated in the revised document below.

"EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that the Chapel Hill WFP was taken off line and it was replaced with a new treatment plant and five new production wells. The new treatment plant started operations on January 27, 2020. System personnel also indicated that monitoring was conducted in November 2019 and the analysis shows that perchlorate was not detected in either the source well water or the finished water."

Thanks
Sam

Thanks Sam.
Do we know exactly what the contractor asked each PWS? Based on this response: **EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that no follow-up/updated monitoring data for perchlorate is available.** It appears we only asked about monitoring…did the contractor ask about any changes in source water and/or treatment too?

Thanks,
Lisa

Subject: FW: Revised Document

Jennifer: Attached please find clean copies of the recommendations and reductions documents for perchlorate. We have incorporated your edits. Please note with respect to your question about CCR reporting of perchlorate monitoring

CCR regulations under 141.153.(d)(1) requires the CCR include data on detected contaminants subject to mandatory monitoring including

i. Contaminants subject to an MCL, action level, MRDL or TT
ii. Contaminants for which monitoring is required under the UCMR
iii. Disinfection byproducts or micriobial contaminants for which monitoring is required.

Therefore if a system monitors for perchlorate outside of UCMR there is no requirement to report it on the CCR. If a system monitored for perchlorate in the UCMR 1 and detected it, then they were required to report it on the CCR for the next 5 years because 141.153(d)(3)(ii) UCMR results "need only be included in CCR for 5 years from the date of last sample or until any of the contaminants becomes regulated and subject to routine monitoring requirements, whichever comes first."
ASDWA is making arrangements for us to speak with the impacted States on Friday and or Monday morning.

Jennifer;
Attached please find revised perchlorate documents. We have revised the perchlorate reductions document with a view towards public release. We have also prepared the attached plan to work next week with ASDWA and AWWA to verify information about the systems and prepare states to assist systems.

Hi Lisa,

We got new information from the MD system. There was some misunderstanding with the information request but here is the latest.

The treatment plant at chapel hill was recently taken off line and it was replaced with new productions wells and treatment plant which started operations in January 27, 2020. Please see the new language that I have incorporated in the revised document below.

"EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that the Chapel Hill WFP was taken off line and it was replaced with a new treatment plant and five new production wells. The new treatment plant started operations on January 27, 2020. System personnel also indicated that monitoring was conducted in November 2019 and the analysis shows that perchlorate was not detected in either the source well water or the finished water."

Thanks
Sam

Thanks Sam.
Do we know exactly what the contractor asked each PWS? Based on this response: **EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that no follow-up/updated monitoring data for perchlorate is available.** It appears we only asked about monitoring…did the contractor ask about any changes in source water and/or treatment too?

Thanks,
Lisa

Let me know if you would like to discuss further. I have asked Sam to get together with Rich to compare the % of systems above the HRL for the negative and deferred reg det 4 contaminants to the % of systems above the potential MCLG/MCL of 18 ppb for perchlorate. I want us to convey how proceeding with the perchlorate regulation is potentially precedent setting and or conflicting with future reg det decisions.

Sam:
Thank you for preparing a revised briefing to respond to the input received in our prebrief. I have made additional edits to address requests received from OW leadership. I have left sections highlighted where OGC input is still needed. I also need you to work with the Regulatory Determinations team to assure we have accurate comparisons of frequency of occurrence in systems at levels above the HRL for Reg Det 4 contaminants and perchlorate occurrence above the MCLG/MCL.
We will not be briefing the Administrator for the next several weeks but we do have an opportunity for OW review of the document so lets try to have revisions next week.
Please include OST on the next version. I have copied Betsy on the attached so that she can see the latest but you should also share with Greg and Jamie.

Hi Eric,

Attached is a revised version of the briefing document, based on Jennifer's direction and comments during last week's meeting. Lisa reviewed this version and provided additional edits. I left two placeholders in this document for the input from OLEM as well as from OGC.

I sent this draft version to Karyn and she is working on providing OGC's input to us. Let me know if you have comments or any suggested edits.

Thanks
Sam

Subject: Perchlorate comment summary
Attachments: Perchlorate Comment Summary V4.docx

Jennifer and Yu Ting:
Attached please find a summary of the comments on the proposed perchlorate drinking water regulation. This issue came up in the hearing prep meeting for the Administrator yesterday and I would like to present the attached in the OW biweekly tomorrow. Please let me know if you have any comments or concerns with the attached.

NPDWR for Perchlorate Proposal: Summary of Public Comments

EPA received a total of 1,495 comments in response to its perchlorate rulemaking proposal.

Mass Mailing Campaign: 1,386 comments were received under a mass mailing campaign. These commenters oppose the proposed Maximum Contaminant Level of 56 µg/L stating that as proposed the MCL is too high to adequately protect the health of communities throughout the country.

Individuals: Eighty-one comment letters with varied levels of complexity were submitted by individuals. These letters cover a wide array of technical and policy issues regarding the perchlorate proposal (88 pages).

6 support the 56 µg/L proposal.
1 supports the 90 µg/L alternative.
6 support the 18 µg/L alternative.
23 support regulation at a level lower than 18 µg/L.
1 supports the withdrawal of the regulatory determination.
44 are in general opposition and/or out of scope.

Extensive and Substantive Comment Letters from Organizations: Twenty-eight comment letters containing extensive and substantive technical and policy issues were submitted (657 pages). The overall recommendation of these comment letters on the regulatory proposal breakdown as follows.

- One organization did not take a position regarding regulation of perchlorate:
  - Association of State Drinking Water Administrators
- None support the proposed 56 µg/L proposal.
- None support the 90 µg/L alternative.
- Two support the 18 µg/L alternative:
  - Oregon
  - Virginia
- Fourteen support regulation at a level lower than 18 µg/L:
  - Association of California Water Agencies
  - Metropolitan Water District of Southern California
  - California
  - Massachusetts
  - New Jersey
  - New York
  - The Salt River Pima-Maricopa Indian Nation
  - The Tohono O'odham Nation
  - Alaska Community Action on Toxics
  - Environmental Defense Fund
  - Environmental Protection Network
  - Environmental Working Group
  - Natural Resources Defense Council
  - American Academy of Pediatrics

NPDWR for Perchlorate Proposal: Summary of Public Comments

- Eleven support withdrawal of the determination to regulate perchlorate:
  - U.S. Conference of Mayors & the National League of Cities (joint letter)
  - South Dakota
  - California Farm Bureau Federation
  - American Water
  - El Paso Water
  - American Chemistry Council
  - American Water Works Association
  - Association of Metropolitan Water Agencies
  - National Rural Water Association
  - Perchlorate Study Group
  - The Chlorine Institute

Appended below is confirmation from Macara's staff that the package went to OP today. (Sent electronically rather than hard copy, per Macara, since this is a revised draft under review.)

The attached Track version (same as provided in clean copy to OW and OP) documents the final round of edits made in SRMD and OGWDW. Lisa C has the email sent to OW with all attachments.

Hi,

Attached are the revised clean versions of the Perchlorate FRN and HRRCA, which incorporate all the suggested edits to date (4-12-19).

Here also you will find a revised redline version which incorporates all edits and changes to the document made to the FRN since the last OW-IO review (3-11-19).

Finally, attached are the most recent version of the corresponding transmittal memos.

Let me know if you have any questions or comments.

Thanks
Sam

Bill
This contains Lindsey's comments which we addressed in the document that was transmitted on Friday. Regarding her schizophrenia comment, we deleted mention of it where she noted her concern (page 14). We have retained the discussion of the Gyllenberg paper later in the document (around page 100 in the document sent Friday) to be comprehensive in our discussion of all the studies examining the link between thyroid hormone perturbation and behavioral outcomes. This is to be consistent with presenting the information that was peer reviewed and to be responsive to comments that did/did not find statistically significant relationships.

Nancy,

Appreciate that there isn't much time to review but we are facing a very tight court ordered timeline to publish a proposed MCLG. That deadline is May 28th and the Administrator is facing a contempt of court citation if we fail to meet that deadline. As you might guess his direction has been clear that we will not put him is a circumstance where he is in contempt of court.

We will certainly add text to clarify the uncertainties and shortcomings of some of the literature in the areas that you identified and incorporate a reference to the agency's data derived extrapolation factors. We did discuss it in the context of cost benefit but can certainly address them in the context of the MCLG.

As for the IQ section – the discussion is there per the direction/agreement with OMB and is the basis of the agreed upon approach to discussion of how to address IQ. It was based on this agreement that they would now accept the draft for interagency review. That general discussion of IQ, and the underlying uncertainty of value to individuals but importance on a population basis, is the intellectual basis for why we are proposing a preferred option of two IQ points but why we are taking comments on values above and below, as well as to withdraw the determination to regulate.

If you believe it is inconsistent with the Administrator's approach on IQ in the context of lead we need to have that discussion with the Administrator, Dave Ross, Alex Dunn and others, ASAP after the draft has gone into interagency review because of the tight timeline we are under regarding the court order.

If you have any other questions please let me know.

Regards,
Lee

Melissa and Lee,
Thanks for the opportunity to review. I am hugely swamped trying to get 2 of our rules and 2 risk evaluations over to OMB so I could only review very quickly.
I looked back at some of our previous comments and flagged a few that I don't think were addressed. I also notice that your team did address many of our previous comments—thank you for that!
I also flagged the new IQ section—It gives me some heartburn based on where the Administrator wanted us to go in our lead rules, so I flagged that for you.

Lindsay may have additional thoughts/more time to review.

Thanks again,
Nancy

Attachments: Perchlorate Comment Summary V3.docx

Thanks Lisa this breakdown is helpful but it pointed out to me that the 109 extensive and substantive letters don't all appear to be summarized.
I think there isn't a need to organize the commenters by organization type and there are some groups that are hard to categorize (i.e. we have ACWA as a regulated stakeholder but AWWA is a trade organization when the both represent drinking water utilities) I also think there is redundancy in the summary of the comments that I tried to eliminate in the attached.
Can the team take a look and see if there are organizations that have submitted extensive and substantive comments that we have not listed and if so please list them in the categories of support that are in the attached.

Subject: RE: draft summary of perchlorate public comments

Hi Lisa,

Here is a revised version which incorporates previously suggested edits.

- We received 6 comment letters in support of the proposed rule at 56 ppb.
- I cannot categorically confirm that the mass mailing campaign was organized by any group, so I am removing that designation from the summary document.
- From the individual substantive letters
  - 1 supports withdrawal option
  - 1 supports 90 ppb option
  - 6 support 18 ppb option
  - 23 support regulation at a stricter level than 18pbb

Thanks
Sam

Hi Sam,
As follow up can you please:

- Confirm we did not get support for regulation at 56 ppb
- Confirm if NRDC is mentioned as the originator of the mass campaign
- Count the 88 individual comments that 1- support withdrawal, 2- support regulation (at any concentration).

Let me know if you have questions
Thanks,
Lisa

Subject: RE: draft summary of perchlorate public comments

Also There are three categories of commenters presented

1. Support withdrawal
2. Support a stricter than proposed standard
3. Neutral

Does this mean there were no commenters in support of the proposed MCLG/MCL?

- ~~Environmental Working Group~~
- ~~Natural Resources Defense Council~~

~~These groups strongly disagree with EPA's rulemaking proposal and the suggested regulatory alternatives. All groups suggest that EPA should set a standard for Perchlorate in drinking water no higher than 2 µg/L. In addition, these stakeholders claim that EPA is not following the statutory requirements of SDWA in that the agency failed to consider an adequate margin of safety while establishing a protective public health MCLG.~~

~~Public Health Professional Organizations~~

~~American Academy of Pediatrics – Disagree with EPA's proposal and urges the agency to set the strongest possible MCLG for Perchlorate.~~

~~3. Organizations that are neutral~~

~~Association of State Drinking Water Administrators – The board has not taken a position on whether to regulate Perchlorate.~~

Lisa:
I am very grateful for the excellent work the Team has done to prepare this revised proposal. I have just a few edits in the attached. I will bring you hard copies of the changed pages to expedite incorporating these edits. As we discussed, at this stage we just need a version that incorporates suggested edits. Please remove the comments provided and we can address them with Jennifer at a later date. This way Jennifer can transmit the revised version to OW and we can send a revised version to OGC.

Thanks

Lisa,
I am so impressed by the quality of the proposal your team put together. The attached includes my edits and comments/questions. If it would be helpful for you all to sit down and go over some of the later, rather than trying to respond in comment bubbles, I'm happy to do that. I am not as well versed on this information as you all so I may have made edits or comments that are not appropriate. If that is the case, please ignore the edit and don't feel the need to explain why.
Thanks much,
Jennifer

Hi Jennifer,
The attached perchlorate proposal addresses my comments and Eric's. We have some additional information we are working on to provide more context for the HRRCA section. This version is ready for your and OW/OGC review. We'll fold in our additional information in the next round of edits.

Let us know if you have questions or concerns.

Dave:
Per your request at Wednesday's OGWDW biweekly meeting, attached please find the most recent version of the Proposed Perchlorate Rule Federal Register Notice. Please note that we provided a prior version to Lee and to OGC last week and while they reviewed the document we continued to make edits to improve clarity. Therefore, the attached version is slightly different from the version provided earlier to Lee and OGC and does not reflect their input.

Please let me know if you have any questions or concerns with the attached.

Hi Sandy,

Thank you for your edits. Your changes have been accepted and two typos corrected as follows:

DR to AW Memo:
Under Impacts: …and administration requirements consisted of the majority of the annual cost.

DR to BB Memo:
This action presents the results of the EPA's economic analysis of the proposed perchlorate regulation and the Agency's conclusion that benefits of the proposed regulation do not justify the costs.

Let me know if you have any questions.

Joe.

Thanks, Sandy!

Note the EO 12866 file is blank – not sure it was intentional.

We'll get you a revised version of the memos.

Joe.

Subject: Use this version - Comments: e-files for the perchlorate pkg
Importance: High

In this version, I also added the San and Rin in the subject line for the Transmittal memo.

Thanks for sending the Perchlorate package. I have a few edits/comments.

1. Thank you for preparing both a transmittal memo and draft action memo. Attached are comments and suggestions.

2. A minor edit regarding the NPRM file name and OMB's requirements. OMB is particular regarding the naming convention. I added the title to the first page of the FRN and changed the title of the Proposed Rule file to

   EO12866_SDWA NPDWR Perchlorate 2040-AF28 NPRM 20190305

3. I removed the first paragraph of the Tribal EO (see below) – which was the 1st paragraph in the old template. I did not change anything else in the body/text of the Tribal EO.

Executive Order 13175, entitled "Consultation and Coordination with Indian Tribal Governments" (65 FR 67249, November 9, 2000), requires the EPA to develop "an accountable process to ensure meaningful and timely input by Tribal officials in the development of regulatory policies that have Tribal implications." The definition of "policies that have Tribal implications" includes regulations that have "substantial direct effects on one or more Indian Tribes, on the relationship between the federal government and the Indian Tribes, or on the distribution of power and responsibilities between the federal government and Indian Tribes." Under Executive Order 13175, the EPA may not issue a regulation that has Tribal implications, that imposes substantial direct compliance costs, and that is not required by statute, unless the federal government provides the funds necessary to pay the direct compliance costs incurred by Tribal governments, or the EPA consults with Tribal officials early in the process of developing the proposed regulation and develops a Tribal summary impact statement.

Please send me the final versions of the memos and I'll print them.

Sandy

Jennifer:
Attached for transmission to the OW IO are revised draft notices for a Proposed National Primary Drinking Water Regulation. The first attachment is a clean version of the revised document and the second is a redline document that shows the changes made since the last OW-IO review.

The changes made to the document include:

1. An additional alternative MCLG and MCL of 90 ug/L based upon a 3 IQ point decrement as the point of departure.
2. Additional text describing IQ and the significance of IQ decrements at the population level.
3. Additional text describing EPA's selection of the proposed MCLG
4. Additional presentation of costs and benefits of the new alternative MCLG/MCL
5. Additional request for comment on the methodology for deriving the MCLG and alternatives.

The attached materials incorporate the comments that we received from you and from OGC. OGC has concluded that the drafts they reviewed "meets the consent decree obligations." Please let us know if you have any questions or concerns with the attached documents.

Jennifer and Yu-Ting:
Attached for your review and comment are the transmittal memos we are preparing to facilitate Inter Agency Review of the propose perchlorate drinking water standard. We will be preparing the "blue folder"package to facilitate getting these documents to the Office of Policy for transmission to OMB for review. Please note that we have been informed that OGC concurrence requires senior level approval now and we do not expect to receive that concurrence today. Also a reminder that the Action memo is a draft at this stage of the process to identify the information we intend to highlight for the Administrator when it is transmitted for signature after OMB concludes Inter Agency Review.

Subject: Follow up from perchlorate meeting

Nancy:
Thanks for your questions at yesterday's briefing on perchlorate, particularly regarding EPA's analysis linking thyroid hormone level changes to IQ decrements. As we discussed, the origin of this analysis was the recommendation of the Science Advisory Board. The SAB stated "The agency should incorporate the appropriate studies related to ingestion of perchlorate, pharmacokinetics of perchlorate, the effects (dynamics) of perchlorate, and dose-response relationships from all the available literature. In developing the pharmacodynamic aspect of this model, the EPA should take advantage of available data on potential adverse health effects due to thyroid hormone perturbations, regardless of the cause of those perturbations, to document and support parameters used in the model. Accordingly, the SAB concludes that these two streams of information — biology of iodide deficiency and perchlorate inhibition of iodide uptake — are complementary and sufficient for the EPA to consider specific life stage factors in deriving an MCLG for perchlorate."
See https://yosemite.epa.gov/sab/sabproduct.nsf/02ad90b136fc21ef85256eba00436459/d3bb75d4297ca4698525794300522ace!OpenDocument&TableRow=2.3#2 for more information.

Also, you asked about the subsequent peer reviews of the work done to implement the SAB's recommendations. As discussed, we performed these peer reviews in accordance with the Agency's guidance on Contractor Lead Highly Influential Scientific Assessments, which provides the public with opportunities to comment on both the peer reviewers and the draft report. Several of the peer reviewers for the contractor lead peer reviews were also members of the SAB panel. The first peer review focused on the BBDR model's ability to predict thyroid hormone changes associated with perchlorate exposure and the second peer review focused upon the changes made to the BBDR model and the evaluation of epidemiologic studies evaluating the relationship between thyroid changes and neurodevelopmental impacts. We sought input from Federal partners on the peer review charges and they provided comments on the draft reports in the public docket.

The Peer review docket including the peer review reports and the public input can be found at https://www.regulations.gov/docket?D=EPA-HQ-OW-2016-0439.

Also attached for your information is the current version of the scientific analysis that responds to the most recent peer review comments. Please let us know if you have any further questions or concerns that you would like to discuss.

Subject: Perchlorate Pre-Meeting Peer Review Summary Report

Hello all,

Please find attached the latest version of the pre-meeting peer reviewer's comments to include Drs. Carrasco and Emond to complete the set (8 of 8).

Let me know if you have any questions.

Regards,
Ahmed

Perchlorate in Drinking Waterv4 7-28-16.pptx

Point of Contact for the Meeting: Lisa Christ 202-564-8354
SCt: Denise Anderson, 564-1782

Purpose: To provide background information on EPA's activities related to the development of a National Primary Drinking Water Regulation for Perchlorate and peer review of scientific reports.

Background: In February, 2011 EPA published a determination to regulate perchlorate in drinking water. In 2012, EPA sought recommendations from SAB on how to derive a MCLG for perchlorate in accordance with SDWA. To address SAB recommendations, EPA and FDA scientist worked collaboratively to develop a Biologically Based Dose-Response model (PBPK model) to inform the derivation of a Maximum Contaminant Level Goal (MCLG) for perchlorate. EPA will conduct an expert peer review of the model, model report and report describing approaches to derive an MCLG in late 2016. EPA will convene a combined peer review process to take advantage of efficiencies and in response to a lawsuit filed by NRDC alleging EPA failed to propose and finalize a NPDWR for perchlorate by the statutory deadline.

EPA Staff (Required): Stan Meiburg, Joel Beauvais, Peter Grevatt, Eric Burneson, Lisa Christ, Daniel Olson, Tom Burke, Laura Vaught

EPA Staff (Optional): Clifton Townsend, Samuel Hernandez-Quinones, Russ Perkinson, Erik Helm, Jessica Georges. Ashley Greene, Ann Campbell
